This entry aims to provide a general description of both reconciliation and third-party affiliation, along with a short description of what conditions might lead to the evolution of such behaviors. Additionally, we describe the form and function of post-conflict affiliation in a broad range of species. Later, the methods used in this field, as well variations in analysis, are discussed.

## Reconciliation and Third-Party Affiliation

As social groups often consist of more individuals than the opponents engaged in a conflict, third parties might also get involved. As such, post-conflict affiliation can be divided into two main categories depending on the participation of third parties: reconciliation (also called post-conflict reunions, or post-conflict opponent affiliation) and third-party affiliation (also called consolation). The functions of these two categories can vary slightly depending on situation and species.

*Reconciliation* takes place between individuals that share valuable relationships, as the benefit from repairing such relationships outweighs the risks that come with renewed aggression upon approach (Aureli et al. 2002). Post-conflict reconciliations mend damaged relationships (Fraser and Bugnyar 2011), reduce stress (Aureli et al. 2002), and reduce the chances of more aggression between former opponents (Fraser and Bugnyar 2011; Lazzaroni et al. 2017). Aureli et al. (2002) described a set of conditions for when post-conflict reconciliation would evolve in a species: (i) individual recognition in relationships, (ii) within-group aggression, and (iii) post-conflict hostility between opponents.

Additionally, for post-conflict reconciliation to be advantageous, there must be a loss of fitness due to the now tarnished relationship between opponents. In other words, post-conflict reconciliation is often seen in species where prosocial relationships between individuals are important for survival. In line with this, reconciliation seems to occur with higher frequency the more valuable a relationship is (Fraser and Bugnyar 2011).

*Third-party affiliation* may provide benefits to third parties and opponents alike. Initiation of third-party affiliations by a loser to a bystander might function to protect a loser from further aggression. Conversely, initiation by a bystander to either of the opponents might function as appeasement of a winning opponent, or as protection of a losing opponent affiliated with the bystander (Koski and Sterck 2009; Yamamoto et al. 2015). Sometimes, post-conflict third-party affiliation works as a substitute to reconciliations when these fail between opponents, providing some comfort and stress reduction (Katsu et al. 2018; Romero et al. 2011; Yamamoto et al. 2020).

## Form and Function of Post-conflict Affiliation

As post-conflict affiliation is a widespread phenomenon among different highly social species in the animal kingdom, the behaviors associated may vary between them. Despite that, the behaviors observed often have more similarities than differences, generally involving physical contact and grooming, as will be elaborated upon in this section.

Post-conflict affiliation and its potential function were first described in chimpanzees by de Waal and van Roosmalen (1979). They noted several affiliative behaviors including kissing, embracing, grooming, and holding out the hand toward the former opponent. Now it is clear that post-conflict affiliations are common in all great apes (Cordoni et al. 2006; de Waal and van Roosmalen 1979; Kopp and Liebal 2018) and also present in other primates, such as macaques

(*Macaca mulatta* and *M. sylvanus*), baboons (*Papio hamadryas* and *P. cynocephalus ursinus*), mandrills (*Mandrillus sphinx*), common marmosets (*Callithrix jacchus jacchus*), and black and white guerezas (*Colobus guereza*) (Bjornsdotter et al. 2000; Cheney and Seyfarth 1997; de Waal and Yoshihara 1983; Patzelt et al. 2010; Robertson et al. 2005; Schino and Marini 2012). Affiliative behaviors are similar between primate species and include behaviors such as kissing, grooming, embracing, genital massage, grasping and clasping, grumbling, grunting, and touching (Arnold et al. 2010).

Spotted hyenas also express post-conflict reconciliation. Here, victims of aggression show a higher tendency to reconcile than aggressors, and kin reconcile more often than non-kin. Hyenas, however, do not reconcile as frequently as primates (Wahaj et al. 2002). Affiliative behaviors take the form of non-aggressive approaches after conflicts and ritualized greetings in which two hyenas stand parallel, facing opposite directions, and sniff or lick each other's penis (or pseudo-penis) under a lifted leg (East et al. 1993; Wahaj et al. 2002).

In domestic goats, post-conflict reconciliation is expressed through muzzle-muzzle and muzzle-body contact as well as allogrooming and standing in close proximity. Both aggressors and victims initiate reconciliation, but aggressors tend to do it more. The frequency of behaviors associated with stress and anxiety dropped in victims after reconciliation (Schino 1998).

In wolves, reconciliation appears initiated between aggressors and victims, as well as between sex and hierarchical status. Additionally, the intensity of a conflict does not affect tendency to reconcile (Cordoni and Palagi 2008). However, other findings suggest that victims tend to initiate post-conflict affiliations and that they exhibit more stress-related behaviors than aggressors after a conflict (Lazzaroni et al. 2017). When expressing post-conflict affiliation, wolves allogroom, play, body rub, sniff, or stand with their bodies in contact. Additionally, they might touch the face of another individual with

their nose or lick another's muzzle when exhibiting affiliation (Cordoni and Palagi 2008; Lazzaroni et al. 2017).

Domestic dogs (*Canis familiaris*) show post-conflict affiliation both in terms of reconciliation and third-party affiliations, and familiar individuals reconcile more often than unfamiliar ones. Third-party affiliations are primarily initiated by third parties and not by victims of aggression. Affiliative behaviors include greeting, sitting and lying in close proximity, anogenital sniffing, playing, and licking (Cools et al. 2008).

Post-conflict affiliation, including both reconciliation and third-party affiliation, has been observed in captive bottlenose dolphins. Reconciliations in dolphins have been suggested to decrease renewed aggression between former opponents (Weaver 2003; Yamamoto et al. 2015); however, some results do not support this (Yamamoto et al. 2020). Third-party affiliation seems to serve the purpose of protecting the loser and appeasing opponents affiliated to the third party (Yamamoto et al. 2015). Bystanders are more likely to console the individual they are most affiliated with, presumably to relieve tension or reduce stress (Yamamoto et al. 2020). Affiliative behaviors include contact swimming with pectoral fin touches, flipper rubbing involving touching with a pectoral fin and subsequently rubbing it across the body of another, and synchronous breathing in which individuals swim together and surface for air at the same time (Yamamoto et al. 2020, 2015).

Few non-mammalian species have been studied for post-conflict affiliation, but good evidence exists for birds, especially corvids. A recent study found reconciliation and third-party affiliation in juvenile carrion crows (*Corvus corone corone*), with aggressors affiliating with victims when aggressions were mild and victims affiliating with third parties when aggressions were severe (Sima et al. 2018).

Common ravens reconcile after aggressive conflicts and do so by contact sitting, allopreening or body or beak touching. Reconciliations occur more often when opponents share valuable

relationships, and renewed aggressions are less likely after reconciliation (Fraser and Bugnyar 2011). Furthermore, ravens console other individuals involved in conflicts if they share a valuable relationship and might thus reduce stress and anxiety (Fraser and Bugnyar 2010).

Rooks (*C. frugilegus*) also appear to be selective with whom they choose to console after a conflict and primarily console their monogamous social partners. The initiation in these third-party affiliations is mutual. No reconciliation has been observed between conflicting opponents, likely because aggression was only seen between individuals that do not share valuable relationships (Seed et al. 2007). When present, post-conflict third-party affiliation has been found to reduce the risk of renewed aggression compared to individuals that did not affiliate with third parties after conflicts (Logan et al. 2013b). However, post-conflict affiliation is not universally found in rooks (Benkada et al. 2020), which might be due to different methods being used.

Post-conflict third-party affiliation is found in jackdaws (*C. monedula*) and jays (*Garrulus glandarius*) but does not reduce the risk of renewed aggression (Logan et al. 2013a), suggesting a different function of post-conflict third-party affiliation in these species (Logan et al. 2013a, b).

Regarding parrots, another very social group of birds, very little research exists. One study on budgerigars (*Melopsittacus undulatus*) identified both reconciliation and third-party affiliation, with males engaging in both types more often than females. Third-party affiliations are mainly initiated by winners and bystanding males toward defeated females (Ikkatai et al. 2016).

Lastly, one example in fish exists. Bshary and Würth (2001) found support for interspecific post-conflict affiliative behaviors between cleaner fish and their various clients. Cleaner fish would utilize tactile stimulation in the forms of touching the dorsal fins of clients with their pectoral and pelvic fins. This behavior was used more often on more dangerous clients in addition to occurring more often when a conflict, in the shape of the cleaner

fish taking a bite off a client, had taken place. These behaviors match the criteria needed to be classified as reconciliation, even with the conflict in question being interspecific and different from other examples (de Waal and van Roosmalen 1979).

## Methods for Studying Post-conflict Affiliation

A problem encountered by anyone studying post-conflict affiliation is the issue of comparing a situation in which a conflict takes place with a situation in which a conflict does not take place, as only one of these two scenarios can happen at a given time between the same two individuals. This problem is what the post-conflict-matched-control (PC-MC) paradigm aims to solve. de Waal and van Roosmalen (1979) first used an early version of this method without the MC constituent on chimpanzees, in which the social interactions of opponents were recorded after a conflict only. This was then later expanded by de Waal and Yoshihara (1983) who added a control observation after a given PC observation on the next possible day, at the corresponding time of day, and for the same duration. Having both PC and MC observations allows for comparisons in frequencies and latencies of behavioral interactions between periods after conflicts and periods with none, while controlling for any differences resulting from circadian or seasonal rhythms. The PC-MC method has become standard in post-conflict affiliation research (Arnold et al. 2010), with some variation in how data has been analyzed. A relatively simple way of comparing PC to MC is by comparing the ratio of “attracted” to “dispersed” observations. PC observations with affiliative behaviors between former opponents occurring earlier or later than PC are labelled as attracted or dispersed, respectively, while no difference would be labelled as neutral (Benkada et al. 2020; de Waal and Yoshihara 1983; Kutsukake and Castles 2004). A significantly higher ratio of attracted to dispersed observations

would then indicate a higher tendency to reconcile after a conflict. It is important to be aware that how PC and MC observations are compared can significantly influence the output of an analysis. For example, Logan et al. (2013a) tested three methods of analyzing post-conflict affiliation: latency, frequency, and duration of affiliation in rooks (*Corvus frugilegus*), jackdaws (*C. monedula*), and Eurasian jays (*Garrulus glandarius*). They found no evidence of reconciliation in rooks and jays but did find some evidence in jackdaws when analyzing affiliation duration. Both rooks and jackdaws showed third-party affiliations for affiliation frequencies and duration, but not latency, while jays only did so for duration. Indeed, a later study did not find any post-conflict affiliation in rooks and found no reconciliation between opponents and no third-party affiliations either. These two studies used different measurements (Benkada et al. 2020). As such, one might benefit from analyzing several measurements, or attempt other experimental setups, to achieve more nuanced results. For example, in species that are vocal in their post-conflict behaviors, playback experiments can provide a way to test the effect of vocalizations in a controlled setting. Playback vocalizations related to post-conflict affiliation can be played for individuals after conflicts, and the frequency of reconciliation thereafter can then be compared to controls. Additionally, differences in reconciliatory tendencies in relation to vocalizations may be compared between aggressors, victims and third parties and their respective controls (Cheney and Seyfarth 1997).

## Conclusions

Since its discovery in the late 1970s, it is now generally accepted that post-conflict affiliation is a widespread phenomenon among highly social species in the animal kingdom. Reconciliation is thought to function as stress relief and repair mechanism for valuable social relationships, while third-party affiliations might function as

victim protection, appeasement of winners, or a replacement of non-initiated reconciliations. Different functions are not mutually exclusive and might differ between species, nuances which deserve further attention. Future studies should explore new methods as well as new ways of analysis of PC-MC data to further elucidate the subtle differences in affiliative behaviors between social species with different life histories.

### Definition

Aureli and de Waal (2000) defined conflict resolution as the actions necessary to either reduce or eliminate incompatibilities present in goals held by differing parties. The literature mentions at least three mechanisms of conflict resolution, including reconciliation, compromise, and sharing (Aureli and de Waal 2000). Reconciliation entails an amicable post-conflict encounter between conflicting individuals that reestablishes their social relationship's stability (Aureli and de Waal 2000). Alternatively, a compromise is reached when the factions involved agree to align, to some degree, their relatively incompatible goals. Lastly, sharing describes the tolerant distribution of a coveted resource among competing factions.

### Introduction

The study of conflict in social primate species is inevitably followed by the study of its consequences. Post-conflict resolution takes many forms, each of which involves behaviors that achieve strategic objectives surrounding the maintenance and strengthening of cooperative bonds throughout a social group. The necessary degree of cooperation depends on which individuals and groups are involved in the conflict and can impact the extent to which reconciliatory acts are attempted. This entry focuses on the general

principles and mechanisms of post-conflict resolution found across many nonhuman primate species and does not instead discuss unique species-specific behaviors. In doing so, the main focus of this entry is on the unique trade-offs associated with conflict and how they are remedied in acts of subsequent conflict resolution. This also allows for a brief overview of the societal structures that give rise to different forms of post-conflict resolution and the subsequent differences found within and between species.

Multiple literature reviews (e.g., Aureli and de Waal 2000; Cafazzo et al. 2018) suggest that reconciliation occurs in an array of nonhuman species. In nonhuman primates, for example, researchers have documented reconciliatory behaviors in Strepsirhini (*Eulemur fulvus rufus*), Platyrrhini (*Cebus apella*), and Haplorhini (e.g., *Cercocebus torquatus*, *Rhinopithecus roxellana*, *Theropithecus gelada*, *Papio anubis*, *Papio hamadryas*, *Macaca arctoides*, *Macaca fuscata*, *Macaca mulatta*, *Gorilla beringei*, *Pan paniscus*, and *Pan troglodytes*, among others). Additionally, several non-primate species have been observed reconciling after a conflict, including ravens (*Corvus corax*), rooks (*Corvus frugilegus*), goats (*Capra hircus*), bottlenose dolphins (*Tursiops* spp.), spotted hyenas (*Crocuta crocuta*), wolves (*Canis lupus*), and domestic dogs (*Canis lupus familiaris*).

### Relationship's Qualities, Reconciliation, and Consolation

De Waal (1996, 2000) developed a *Relational Model* for understanding conflict and reconciliation. Per this perspective, social partners may adopt one of three behavioral strategies in response to a conflict of interest: (1) tolerate their partner's goal, (2) adopt an aggressive stance, or (3) avoid any physical or social interaction with their peers. The model also claims that reconciliation is possible when individuals manage to align their previously conflicting interests. Furthermore, de Waal's model argued that the outcome of a conflict of

interests is moderated by the social context and the partners' attributes (i.e., social value). Consequently, when two or more individuals compete for resources, the parties involved must evaluate the value of the resource relative to the risk of suffering an injury (i.e., net benefit) and the potential harm this conflict may inflict upon their relationship. It follows then that the resource value must be greater than the more considerable imbalance of power between opponents, or the relationship value, to compensate for the potential costs accrued during the conflict. In contrast, if the opponents can reduce the damage inflicted upon the relationship once the confrontation is over (i.e., *reparability function*), then the likelihood of open conflict between the parties involved increases considerably (de Waal 1996, 2000). De Waal's model postulates that the value of the resource, the relationship's reparability, and the chances of competition all positively predict the frequency of agonistic interactions. In contrast, an individual's inclination toward aggressive exchange decreases with the probability of suffering an injury and the relationship's value.

Other authors have developed similar theoretical models (Aureli et al. 2002; Aureli and Schaffner 2006; Silk 2002). For instance, Cords and Aureli (2000) proposed that the qualitative dimension of a relationship is associated with post-conflict resolution. The authors generated a taxonomy of qualities that included (1) the social partners' value, (2) the relationship's security, and (3) the partners' compatibility. In terms of the notion of value, Cords and Aureli claimed that individuals generally benefit from maintaining social bonds with other group members (goods and services ranging from access to mates and food to social support during agonistic interactions). Consequently, the greater the risk of losing access to relevant goods or services, the greater the willingness to reestablish an affiliate interaction with the afflicted party. It is worth noting that even though subjects are significantly biased toward repairing a high-value relationship, this does not preclude them from reconciling with a less valuable partner. According to Cords and Aureli (2000), post-conflict affiliative interactions with low-value conspecifics decrease the probability of agonistic escalation wherein high-ranking allies are dragged into the conflict. For example, a

mid-value adult may reconcile with a low-value juvenile if the youngling is part of a high-ranking lineage. Such a tactic reduces the probability that the youngling's high-status kin will antagonize the mid-ranking adult in the future.

In addition to limiting the risk of a negative spillover effect, reconciliation with low-value individuals also facilitates the emergence, or consolidation, of bonds with high-value partners. For instance, it is not uncommon for unaffected parties to be drawn near a dyad in the process of reconciliation; hence, under such circumstances, an individual can indirectly benefit from repairing its relationship with a low-value partner by developing new coalitions and alliances with more valuable conspecifics. Besides a partner's value, Cords and Aureli (2000) also argued that the relationship's security influences reconciliation probability. The authors described the notion of security as an individual's confidence concerning its relationship stability over time. Hence, a subject involved in a secure relationship can predict the behavior of a social partner accurately. Security, just like value, is not necessarily symmetrical. For instance, two social partners may differ in their predictability levels. Per Cords and Aureli (2000), individuals are expected to seek reconciliation after a conflict when the relationship is less secure and of considerable value. In addition to value and security, the third and last relationship quality factor, *compatibility*, is based on the shared history of social interactions and the dyad's shared temperament. It is worth noting that partners may differ in the interpretation of their degree of compatibility based on their relationships with other individuals in the group. Thierry and collaborators (2008) collected ethological information on conflict resolution from 15 groups of nine macaque species. In addition to employing traditional statistical procedures, the authors used comparative phylogenetic methods to determine the degree of variation in counteraggression, conciliatory behaviors, and kin bias in macaques. The authors defined counteraggression as the percentage of times the recipient of aggression reacted aggressively. Alternatively, Thierry et al. (2008) operationalized the concept of conciliatory tendencies and the behavioral inclination toward establishing amicable interactions among former opponents. According

to their publication, kin bias was estimated as the proportion of conciliatory tendencies between kin relative to the total number of conciliatory events (equal to the sum of kin and nonkin conciliatory events). A series of ANOVAs identified no significant differences within groups of the same species, whereas the models did detect considerable species differences in counteraggression and conciliatory tendencies.

As part of their study, Thierry et al. (2008) assessed the trait's preservation with two phylogenetic signal metrics, Pagel's  $\lambda$  and Blomberg's  $k$ . These measures indicate whether closely related species feature similar phenotypes due to shared common ancestry (i.e., trait preservation). As expected, the analyses detected that conciliatory tendencies and acts of counteraggression were phylogenetically preserved. Using phylogenetic independent contrasts, a procedure that accounts for underlying phylogenetic effects, Thierry et al. noticed a significant and positive correlation between the species' counteraggression and conciliatory tendencies. The comparative phylogenetic model did not detect a significant relation between counteraggression and kin bias. Overall, these results suggest that frequent agonistic interactions coevolve with nonkin reconciliatory behaviors. Hence, post-conflict resolution reduces the probability of group dissolution due to within-group competition among nonrelatives.

Besides reconciliation, several researchers have claimed that post-conflict consolation also occurs across nonhuman species. De Waal and van Roosmalen (1979) were the first to define the concept of consolation as a rise in the frequency of affiliation between third parties and the target of aggression after the culmination of an agonistic interaction. Although consolation, relative to reconciliation, is less prevalent in nonhuman primates, several publications have reported its occurrence in platyrrhines (*Cebus apella*) and haplorhines (*Papio hamadryas*, *Gorilla beringei*, and *Pan troglodytes*). Given the prosocial nature of consolation, researchers faced challenges in explaining the evolution of this behavior. De Waal and Aureli (1996) generated two evolutionary hypotheses, the Social Cognition Hypothesis (SCGH) and the Social Constraints Hypothesis (SCSH). Under the

SCGH, empathy and metalizing abilities facilitate the rise of consolation among nonhuman primates. Hence, species either lacking or featuring limited empathic abilities will be less prone to consoling others after a confrontation.

In contrast, the SCSH argues that the probability of consolation depends on whether third parties may become the target of aggression if they affiliate with one of the parties involved in a previous conflict. This hypothesis also predicts that consolation will occur between parties if the potential gains are higher than the costs of performing this behavior. De Waal and Aureli (1996) also argued that the risks depended on the power imbalances between the parties involved. Societies that frequently enforce a strict dominance hierarchy and discourage affiliation with low-status individuals generally lack consolation.

## Discussion

Although social groups provide individuals with an array of benefits, from protection against predators to defense against rival groups of conspecifics, gregariousness is also associated with the inevitable competition for finite resources (e.g., including social and mating partners, food patches, and resting spaces). An increased frequency and severity of agonistic interactions pose a threat to societal cohesion. Hence, several social species feature various behavioral tactics destined to repair a social relationship once a conflict culminates, as observed in numerous clades ranging from corvids to eutherian mammals (Cetartiodactyla, carnivorans, and several nonhuman primates). The empirical evidence supports the predicted positive coevolution between counteraggression and post-conflict resolution, suggesting that highly despotic societies also exhibit the necessary social relays to restore group stability.

## Postcopulatory Intersexual Selection

### ► Cryptic Mate Choice

## Postcopulatory Selection

Matilda Brindle

University College London, London, UK

## Synonyms

[Cryptic female choice](#); [Sexual selection](#); [Sperm competition](#)

## Definition

Postcopulatory selection is an evolutionary process based on sperm competition and cryptic female choice.

## Sexual Selection

While **natural selection** favors genes that aid survival, **sexual selection** results in the evolution of traits that give individuals an advantage in gaining access to and mating with members of the opposite sex. The process can be intra- or intersexual and occur pre- or postcopulation.

**Intrasexual selection** acts upon members of the same sex who compete for access to the opposite sex. This typically emerges as male-male competition, because of the high reproductive potential associated with producing numerous small gametes (sperm). Consequently, females are the limiting factor for male reproduction.

**Intersexual selection** occurs when individuals of one sex prefer particular members of the opposite sex. This typically emerges as female choice, because of females' comparatively limited number of relatively large gametes (ova) and associated high investment in offspring which, in the case of mammals, includes gestation and lactation. These dynamics create different **reproductive strategies** between the sexes.

Thus, males can maximize reproductive success by mating with many females, while females can maximize reproductive success by choosing high-quality males in terms of genetic makeup

and/or their ability and willingness to invest in offspring.

## Postcopulatory Selection

Within the sexual selection framework, precopulatory selection can be understood as affecting mating opportunity, rather than fertilization – both intrasexually (access to opposite-sex mates) and intersexually (attractiveness to the opposite sex). Similarly, postcopulatory selection reflects intrasexual pressure (typically, via male-male **sperm competition**) and intersexual pressure (typically, via cryptic female choice), but affects fertilization success once mating is achieved.

Fertilization can take place within a female (as in most mammals, reptiles, and birds) or externally (as in many amphibians and fish). Copulation is a form of internal fertilization by which a male introduces sperm directly into a female's reproductive tract. In the case of vertebrates, this is either a vagina or cloaca. Postcopulatory selection is still present in species which do not copulate, such as externally fertilizing species, but happens outside of the female.

Sexual selection after fertilization, for example through abortion or infanticide, tends to reflect competing interests between parents and other individuals, and is therefore not traditionally grouped with postcopulatory selection *sensu stricto*.

## Sperm Competition

Sperm competition is the contest between the sperm of two or more males for the fertilization of a female's ova (Parker 1970). Other things being equal, mating with a greater number of females will increase a male's reproductive success. This not only results in high levels of precopulatory somatic male-male competition, via mechanisms such as weaponry, but also in postcopulatory selection via sperm competition, which influences, among other things, genital morphology and sperm quality and quantity (Birkhead and Pizzari 2002).

The lottery principle suggests that the more sperm a male deposits inside the female reproductive tract, the greater their chances of successful fertilization (Dixson 2012). For instance, male golden hamsters that ejaculate more frequently with a female father more of her offspring (though other factors such as mating order and male genotype can also have an effect). If increased numbers of sperm per ejaculate are advantageous, a corresponding increase in testes size is often found (Harcourt et al. 1981). For example, female chimpanzees tend to mate with multiple males in short succession, whereas female gorillas tend to mate with a single male. Consequently, chimpanzee testes are relatively much larger than those of gorilla males. Similarly, within different species of howler monkey, testes mass increases with group size, while the volume of the hyoid bone (that facilitates the species' typical calls) decreases – illustrating a trade-off between precopulatory (via vocalization) and postcopulatory (via sperm) competition (Dunn et al. 2015). This highlights the potential for strategic allocation of sperm in response to the level of sperm competition. Indeed, male feral fowl increase the number of sperm they allocate to a female when there are more male competitors (Davies et al. 2012).

Sperm morphology and function is likewise affected by sperm competition. For example, increased sperm motility is thought to benefit males in populations where male-male competition is high. Certain molluscs produce a large, nonfertilizing sperm morph called a spermatzeugma that, on its tail, carries hundreds of ordinary spermatozoa up the female's reproductive tract (Dixson 2012). The semen of *Drosophila melanogaster* flies contains proteins from the accessory gland that increase a female's rate of egg laying, decrease her receptivity to remating, and remove or destroy sperm of males she has previously mated with (Davies et al. 2012).

Sperm competition can also act on genital morphology, as exemplified by the complex penile morphologies found in species experiencing high degrees of postcopulatory selection (Dixson 2012). For instance, some primates have exaggerated mushroom-shaped or tapered penises and

keratinized penile spines (thought to compound plugs of coagulated ejaculate, remove the plugs of rival males, and stimulate females, respectively). The baculum (penis bone), a structure that supports the penis and facilitates sperm transport toward the cervix, has coevolved with multi-male/multi-female mating systems across the course of evolution in primates (Brindle and Opie 2016). Moreover, species with high levels of male-male competition tend to have longer bacula than species without.

Genital morphology can also help sabotage the reproductive efforts of competitors. Male ebony jewelwing damselflies have two specialized scoops at the end of their penises, which are used to remove sperm left by previous males before they deposit their own (Davies et al. 2012). Male cave bat bugs “traumatically inseminate” females by injecting sperm directly into their bodies. This sperm then swims around inside the female until it encounters her eggs. Occasionally, males mount and inseminate one another homosexually. In these instances, it is believed that the sperm may then migrate to the victim’s testes, ready to be passed on to the next female they mate with (Davies et al. 2012).

## Cryptic Female Choice

Sperm competition generates potential for females to discriminate between sperm of different males in a process known as cryptic female choice (Birkhead and Pizzari 2002). The associated mechanisms are difficult to establish, since the choice is “cryptic.” It is very subtle, often occurs within the female reproductive tract, and is frequently concealed by male-driven processes; definitive examples, therefore, are hard to come by. However, we expect such choice to be pronounced if a female has only limited pre-copulatory mate choice, such as when macaque females mate with multiple males, or when females are coerced to copulate, as frequently takes place in certain waterfowl.

Various mechanisms of cryptic female choice have been proposed. Examples include differentially rejecting or facilitating the uptake of sperm,

storing sperm before fertilization (to enable selection between males), or altering the chemical environment within the reproductive tract (to be more or less favorable to a given male’s sperm).

Cryptic female choice can be directional, by favoring the sperm of mates with preferred phenotypes, or nondirectional, by preferring the sperm of mates with compatible genotypes, irrespective of their phenotypes. However, in practice, it is difficult to disentangle which type is occurring. Directional choice may occur in feral fowl where females copulate preferentially with high ranking males, yet are sometimes coerced by subordinates (Birkhead and Pizzari 2002). If coerced, females emit a distress call, attracting a dominant male who displaces the subordinate. If calls do not work, females may eject the non-preferred ejaculate via cloacal contractions. Nondirectional choice is illustrated by the comb-jelly Beroë, an oval-shaped marine invertebrate, where numerous sperm may simultaneously penetrate an egg (Birkhead and Pizzari 2002). The egg’s nucleus then travels toward each sperm in turn, apparently assessing them individually before “choosing” which one to fuse with.

As well as enabling unsuitable males to be rejected, cryptic choice can also favor desirable mates. In humans, female orgasm is thought to boost sperm transport, retention, and activation, as well as potentially inducing male ejaculation (Puts and Dawood 2006). Corresponding physiological responses are present in other female primates (Dixson 2012), raising the possibility that female orgasm reflects cryptic choice. Indeed, in Japanese macaques, female orgasm is particularly likely when low-ranking females copulate with high-ranking males, with corresponding low frequency during copulations of high-ranking females with low-ranking males (Troisi and Carosi 1998). In primates, female masturbation before or after copulation with a preferred male may also function as cryptic choice, as the physiological changes to the reproductive tract concurrent with arousal tend to be favorable toward sperm.

Given the differential reproductive strategies of males and females, cryptic choice is likely to provoke counterselection in males, aimed to

influence the outcome of female discrimination. One example of this is antagonistic genital coevolution, a process which may explain why male genitalia diverge faster than other morphological traits (Eberhard 1993). In some waterfowl, for instance, males have elongated, spiny, anticlockwise coiled penises that they evert directly into females. Females have evolved equally morphologically complex vaginas that coil clockwise and contain “dead-end” chambers. If a female does not want to mate with a male, she can contract her muscles in such a way as to block his penis from fully everting or send it down a “dead-end” chamber. If she wants to mate with a male, she can position herself in such a way that he can fully evert his penis, so that the sperm is more likely to reach her cervix.

Thus, sex-differential reproductive strategies and the associated conflicts between the sexes influence not only precopulatory contexts, but also exert their influence after mating has occurred.

## Conclusion

Inter- and intrasexual competition does not stop once copulation begins, as evidenced by adaptations in both males and females on the level of behavior, morphology, and physiology. Sperm competition enables males to continue to compete with one another for fertilization of a female at the cellular level, while cryptic choice gives females a degree of control over which males father their offspring. The interplay between these evolutionary processes has given rise to an extraordinary array of phenotypic diversity, deserving of further investigation.

## Definition

Act of fertilizing an egg after the death of one of the parents (usually, the male).

## Introduction

While most eggs are fertilized using the sperm of live males, fertilization after the death of the father is known in a variety of animals. This is possible in internally fertilizing species which, to different degrees, present adaptations to enhance the survival of sperm for the period of time between ejaculation and egg fertilization. This period is known to vary from mere hours in common rats *Rattus norvegicus* to more than 10 years in some species of ants (Orr and Brennan 2015). Large periods of sperm survival are possible in many species because females sometimes present natural mechanisms of sperm storage that allow them to fertilize their eggs long after mating with a male and, thus, allow for the possibility that a male can conceive offspring well after death. Posthumous fertilization using stored sperm is commonly observed under laboratory conditions. For example, laboratory-reared fruit flies *Drosophila melanogaster* can store sperm for up to 2 weeks, approximately a third of their lifespan. Many aquarium female poeciliid fish, such as mollies and guppies, can reproduce monthly for up to a year after removing males from the tank; and captive painted turtles *Chrysemys picta* can store sperm for up to 3 years.

In some cases, such as humans and domestic species, technology allows for posthumous fertilization of species without natural mechanisms. This has been thanks to the development of artificial methods of sperm extraction, preservation, and insemination. Posthumous reproduction in humans brings about moral, ethical, and legal implications that remain subject to debate and controversy. In this piece, we focus on describing posthumous fertilization in wild animals.

## Posthumous Fertilization in Natural Populations

Despite the numerous examples in captivity and the ubiquity of sperm storage mechanisms across the animal kingdom, its cryptic nature can make it hard to study in the wild. Therefore, little is known about the importance of sperm storage and posthumous fertilization in natural

populations. Because many species show a clear bias toward the success of younger sperm, it is often assumed that posthumous fertilization is not very common in nature. A handful of examples, however, point out that it may be more important than previously believed.

The most extreme known case of posthumous fertilization through female sperm storage occurs in leaf-cutting ants. Colony-founding queens of the ant *Atta colombica* mate with several males (also known as drones in social insects) during a single flight mating period to obtain their lifetime supply of sperm (Fig. 1). Males die soon after the mating and their sperm is stored in specialized female organs called spermatheca. This sperm will sire all the sexual offspring produced by the queen in that colony, which can be over a period of 10 years or more (Baer et al. 2006). In this example, all males compete simultaneously for matings while alive and then fertilize females after death.

Other examples show a more dynamic interaction between the fertilization success of live and dead males. Such is the case of the Trinidadian guppy *Poecilia reticulata*, a small freshwater fish inhabiting neotropical montane streams (Fig. 1). Female guppies have small receptacles in the ovarian cavity that can store and nourish sperm. A recent demographic analysis of female guppies in the wild shows that this allows males to reproduce for up to a year after their death, and that up to 25% of births are conceived by dead males (López-Sepulcre et al. 2013). In side-blotched lizards *Uta stansburiana* (Fig. 1), this competition for fertilization between live and dead males is associated with alternative mating strategies. Lizards in this species have three different male morphs: orange-, blue-, and yellow-throated. While orange- and blue-throated males specialize in courting and guarding females, yellow-throated males specialize in sneak copulations and invest in postcopulatory sperm competition, thus showing higher levels of posthumous fertilization success (Zamudio and Sinervo 2000).

## Mechanisms of Sperm Storage

There is a large diversity of sperm-storage adaptations, varying in complexity, across the animal

**Posthumous Fertilization, Fig. 1** Three examples of species where the dynamics of posthumous fertilization has been studied in the wild. From top to bottom: the leaf-cutter ant *Atta colombica* (Photo: Christian R Linder), the Trinidadian guppy *Poecilia reticulata* (Photo: Amy Deacon), and the side-blotched lizard *Uta stansburiana* (Photo: Judy Gallagher). All photos were downloaded from Wikimedia Commons and are reproduced under a Creative Common License

world. In most cases, sperm storage is accomplished by the use of a spermatheca: the specialized sperm storage organ in the female reproductive tract present in many taxa including worms, insects, and amphibians. In the absence of specifically derived storage organs, some organisms store sperm in modified tubules or other parts of the female anatomy, initially only used for

other functions of reproduction. Examples of this include the small ovarian pockets in guppies, or the modified epithelial cells, oviduct, or ovarian folds in certain marsupials and skinks. In some cases, these can be combined with nutritious secretions that prolong sperm survival beyond male death. Such is the case of the albumin-secreting glands used in certain species of turtles (Orr and Brennan 2015).

Not all sperm storage adaptations involve morphological changes in the female reproductive anatomy. Females of some species have evolved modified immune systems, which enable them to locally suppress any outside invaders or infection to their body, while at the same time tolerating the presence of invading sperm for long periods of time (Holt and Fazeli 2016). In some organisms, such as ants, however, this immune suppression can also lead to a cost in overall immune function (Baer et al. 2006).

Males can also evolve certain modifications to prolong sperm survival in the female reproductive tract. This includes the presence of antimicrobial agents in their ejaculate, or the production of sperm that reduce their movement during storage, but which can restore activity quickly once the female is ready for egg fertilization (Orr and Brennan 2015).

The above examples highlight an interesting fact: in many cases, the evolution for greater sperm storage capacity in females is coupled with the evolution of sperm modifications in males. For example, in many species of *Drosophila* or diopsid stalk-eyed flies, this coevolution between males and females has led to the evolution of increased sperm length being tightly correlated with the evolution of increased size of the female reproductive tract (especially spermatheca size), or the use of directed female muscular contractions to move the sperm more efficiently into sperm storage locations (Presgraves et al. 1999).

## Evolutionary Causes and Consequences

The evolution of posthumous fertilization needs to be understood as the product of two selective processes: (1) selection on males for sperm longevity, and (2) selection on females for the

development of mechanisms such as sperm-storage organs and sperm nourishment.

The advantages for males of posthumous reproduction through sperm storage are obvious. Sperm storage prolongs the reproductive life while avoiding the maintenance costs of survival (metabolism, antipredatory behavior, etc.). This can be particularly important in seasonal environments where surviving from one reproductive season to the next can be highly costly. In other words, if sperm can survive in the reproductive tract of females, and females have a higher resilience to environmental changes, it may be advantageous to invest in posthumous reproduction rather than adult survival. However, storing sperm incurs costs to females ranging from the allocation of resources to sperm storage (both in terms of the development of structures and the nourishment of sperm), or the previously mentioned potential immune costs due to the need to avoid the recognition of sperm as a foreign entity to eliminate. This means that the evolution of female sperm storage through natural selection requires that the advantages outweigh the costs. Unfortunately, there is little research in this area.

One proposed advantage is that sperm storage allows females to ensure a sperm supply when the access of males is unpredictable. Moreover, this strategy allows for the accumulation of genetically diverse sperm, thus increasing the probability of adapted offspring in a variety of environments, especially the more unpredictable ones. Posthumous fertilization also has important evolutionary and ecological consequences. As the importance of sperm storage increases, so does the strength of postcopulatory selection (i.e., competition among sperm) and the potential for cryptic female choice (Devigili et al. 2016). Moreover, posthumous reproduction may help maintain high effective population sizes despite high male mortality.

## Conclusion

Sperm storage is ubiquitous in species with internal fertilization, allowing for males to reproduce beyond death. While much is known about this potential in captive populations, the study of

posthumous fertilization and reproduction in the wild is difficult, and its evolutionary origins and consequences are poorly understood. Recent developments of genetic and statistical techniques, however, have provided us with examples demonstrating that it can be an important process in the dynamics of animal populations.

## Introduction

The human genome consists of around 25,000 genes, and the proteins synthesized from these genes are in million. This protein diversity can be explained by the process of PTM, which are not gene-template based (Walsh et al. 2005). The nascent proteins or polypeptides formed as a result of translation from mRNA are biologically inactive. To achieve its biological active form, these proteins undergo certain covalent and enzymatic modifications in the final stage of protein synthesis. These modifications are termed as Post Translational Modifications (PTM). PTM includes folding of newly formed polypeptide chain to its proper three-dimensional conformation, removing of one or more amino acids, addition of certain chemical groups to some individual amino acid residues, and proteolytic cleavage and/or attachment of prosthetic groups to its amino or carboxyl terminals.

## Protein Folding

After translation, newly formed polypeptides with primary structure undergo conformational changes to attain its biological active tertiary/

quarternary structure with the help of Chaperons. Improper folding leads to nonfunctional protein which tends to accumulate in various protein misfolding diseases.

## Biological Functions of PTM

Post translational modifications of proteins can regulate the protein functions, by causing changes in protein activity, their cellular locations, and protein-protein interactions. It also plays a major role in xenobiotics.

These modifications include many mechanisms like glycosylation, prenylation, phosphorylation, acetylation, methylation, SUMOylation, amidation, myristoylation, farnesylation, cysteine oxidation, and ubiquitinylation. Most of these processes are reversible and modulate the protein function significantly. Few types of modifications are explained below.

- A) **Glycosylation:** It plays a major role in many cellular functions, e.g., signal transduction, immune response, cell-cell interaction, and hormone actions. Carbohydrate side chains of glycoproteins are attached covalently to polypeptides. N-linked glycosylation, O-linked glycosylation, C-linked mannosylation, and glypiation are four major type of glycosylation. N-linked and O-linked glycosylation are most common. In some glycoproteins, the carbohydrate side chain is enzymatically attached to Asn residue (N-linked oligosaccharides). O-linked monosaccharide modification of N-acetylglucosamine on Serine, Threonine, or amino acid residue in close proximity to tyrosine phosphorylation sites is frequently observed in many cells.
- B) **Isoprenyl group addition:** A thioether bond forms between isoprenyl group (groups derived from isoprene) and a Cys residue of the protein. Isoprenyl group helps protein to anchor in the membrane, e.g., Ras proteins, trimeric G proteins, and lamins.
- C) **Phosphorylation:** Certain Ser, Thr, and Tyr residues are enzymatically phosphorylated by ATP at their hydroxyl group. This

reversible phosphorylation plays a crucial role in signal transduction pathways (Hunter 2000; Olsen et al. 2010; Chiarugi and Cirri 2003; van Montfort et al. 2003).

- D) **Hydroxylation:** Hydroxyproline and Hydroxylysine in collagen are formed due to hydroxylation of Proline and Lysine, respectively.
- E) **Carboxylation:** Glu residue of some proteins, e.g., blood clotting protein Prothrombin, contains carboxyl groups added enzymatically during PTM.
- F) **Addition of prosthetic group:** Prosthetic Group is a nonprotein organic molecule which is bound covalently to protein for their proper functioning, e.g., biotin molecule of acetyl-CoA carboxylase and heme group of hemoglobin or cytochrome C.
- G) **Proteolytic cleavage:** Many proteins are initially synthesized in their Pre-pro-form, which is larger and inactive precursor protein (zymogens). These undergo cleavage to form smaller and active proteins. Examples of such proteins include Insulin, trypsinogen, and chymotrypsinogen.
- H) **Disulfide bond formation:** Some proteins form disulfide bonds between interchain or intrachain Cys residues. It is common among proteins to be exported from the cells.
- I) **Ubiquitinylation:** Attachment of ubiquitin to certain lysine residues in target proteins marks them for degradation (Wilkinson 1987).

## Techniques to Study PTM

Difference in charges, molecular weight, half-life, and many other physical and chemical properties occur during PTM. These PTMs have been extensively studied and characterized through systemic analysis by mass spectrometer and new analytical techniques (Cantin and Yates 2004).

## Perspectives

PTM plays a major role in various cellular functions. To understand more specifically

about the interface between PTM and its biological functions, significance of altered PTM in disease pathogenesis may be beneficial in developing innovative treatment options.

## Introduction

The precedence effect encompasses several phenomena that influence sound perception and localization when multiple sound sources arrive at the listener in close succession (Brown et al. 2015; Litovsky et al. 1999). For a range of delays between a leading (i.e., first arriving) and lagging (i.e., later arriving) stimulus that arrive from different directions, receivers tend to perceive only a single sound source, a phenomenon known as fusion. When leading and lagging sounds are presented simultaneously or at extremely short delays, a single fused sound is perceived, but the sound's location is perceived to be somewhere in between the actual location of the two sound sources, a phenomenon known as summing localization. At longer delays, receivers tend to perceive this fused sound as originating from the location of the leading sound source, a phenomenon known as localization dominance. Finally, as the delay between leading and lagging sounds increases beyond what is termed the echo threshold, receivers perceive both the leading and lagging sounds as separate images. Leading sounds can not only affect sound localization but also the ability of receivers to discriminate characteristics

of the lagging sound, a phenomenon known as lag discrimination suppression.

## Functional Significance of the Precedence Effect

The precedence effect in humans is generally thought to be a directional hearing mechanism that allows for the perception and localization of sounds in reverberant environments (Wallach et al. 1949). Fusion and localization dominance may reduce the influence of echoes arriving somewhat later and from different directions than sound originating from the source. Psychophysical studies of the various phenomena comprising the precedence effect in humans have shown that the specific time delays at which each phenomenon takes place vary with factors including stimulus duration, frequency, and interstimulus angle, whether stimuli are presented in the azimuthal or median sagittal plane, subject age, previous experience, and hearing capabilities (Litovsky et al. 1999).

The precedence effect also appears to be widespread in animal hearing, although its ecological relevance is less clear. In certain environments, reverberations may be as problematic for animals as they are for humans in buildings. However, in many other cases, reverberation is probably a less serious problem for sound localization than the presence of noise from both abiotic sources such as wind and flowing water and that produced by other signaling animals, as well as general sound attenuation and degradation through the environment. Nevertheless, there is conclusive evidence for one or more of the phenomena associated with the precedence effect in such disparate taxa as crickets, flies, frogs, birds, and mammals (Lee et al. 2009). Furthermore, in many cases, the time delays at which localization dominance and echo thresholds occur are similar in human and nonhuman animals. Precedence effects may be a general adaptation for auditory scene analysis and directional hearing in noisy and complex acoustic environments, which is a fundamental problem in animal communication.

## Methods for Studying the Precedence Effect

In humans, the precedence effect is most often studied by presenting subjects with acoustic stimuli using either headphones or loudspeakers that vary in their relative timing or another relevant characteristic, and having the subjects report on various aspects of their perception of the stimuli (e.g., for fusion and localization dominance, whether one or two stimuli were perceived and where the stimulus was perceived to have originated, respectively). In nonhuman animals, the subject's perception cannot be reported verbally, and most studies rely on either conditioning protocols or on responses that are an important component of the species' natural behavioral repertoire (e.g., phonotaxis toward mate attraction signals, predator-avoidance responses, and orientation toward prey sounds). Animal studies are also used in neurophysiological investigations of the precedence effect. Indeed, correlates of the precedence effect have been found in most areas of the ascending auditory system, although certain precedence effect phenomena may only arise in more central processing centers. The inferior colliculus has been proposed to be a particularly important brain region for the generation of the precedence effect in mammals (Tollin et al. 2004), but the precedence effect is much more taxonomically widespread and may involve different neural mechanisms in other taxa, particularly insects.

## The Precedence Effect and Preferences for Leading Signals in Mate Choice

In behavioral ecology studies, the term "precedence effect" is also used in a somewhat looser manner to refer to the observation that in mate choice, choosing individuals are often attracted to the first arriving of two mate attraction signals (Greenfield 2005). These leader preferences are behaviorally analogous to some aspects of the psychophysical precedence effect because they result in the animal orienting toward the leading of two signals, often with no apparent influence from the lagging signal. However, in only a few

cases has it been demonstrated that the precedence effect (*sensu stricto*, as defined in the Introduction) is the mechanistic basis for such leader preferences (Marshall and Gerhardt 2010). Leader preferences could also arise because leading signals suffer from less masking. Furthermore, even if both signals are equally well-perceived as separate signals, a leader preference could be expressed if leading signalers are of higher quality and are therefore preferred as mates. The delays over which leading signals are preferred to lagging signals in mate choice are often much longer than echo thresholds measured with psychophysical protocols in the laboratory, although these two measurements are rarely carried out on the same species. It is therefore unclear if the precedence effect can account for leader preferences, although neither can it be ruled out because most psychophysical studies use simplified click stimuli, whereas most mate selection involves much more complex signals; echo thresholds depend strongly on stimulus characteristics.

In any event, it has been argued that precedence effects may be a general adaptation to localize an individual signaler among many competing signals, and this is a common situation faced by animals choosing mates. Comparative studies could reveal if the time course of various precedence effect phenomena varies across species and if this relates to the challenges associated with mate localization. Furthermore, regardless of the mechanistic basis, leader preferences appear to be an important mechanism behind the striking temporal patterning observed in many signaling assemblages. Such assemblages are often characterized by highly precise synchrony or alternation of signals and leader preferences, perhaps caused by the precedence effect, selected for competitive signal timing strategies that generate temporally structured choruses as epiphenomena (Greenfield 2005).

## Precedence Effects and Perception in Complex Natural Environments

The precedence effect is just one of many mechanisms facilitating the localization and

discrimination of signals in complex environments, and recent studies suggest that these mechanisms likely interact. Most of these studies have been carried out in humans, but the same phenomena are likely to be found in non-human animals facing similar ecological challenges. First, the precedence effect has recently been demonstrated in humans to be affected by visual input. Cross-modal integration of visual and acoustic stimuli can alter the localization of leading and lagging acoustic signals depending on which of these stimuli is in spatial proximity to the visual stimulus (Bishop et al. 2011). This phenomenon has only been tested in one non-human animal, the gray tree frog *Hyla versicolor*, which experiences the precedence effect but for which there was no evidence of cross-modal integration of visual and acoustic stimuli (Reichert et al. 2016). Interestingly, orientation toward leading signals has also been demonstrated in the visual modality alone: female fiddler crabs evaluate males' claw waving displays and prefer males whose waves lead those of other nearby individuals (Reaney et al. 2008). Many animals evaluate multimodal signaling displays containing both visual and acoustic information, and it would therefore not be surprising if both modalities contributed to localization, potentially via the precedence effect. Second, the precedence effect in humans is strongly affected by recent experience, and the strength of the precedence effect in the perception of any given stimulus can be built up by previous experience with the same stimulus (Litovsky et al. 1999). This buildup, however, can be broken down if the spatial characteristics of the stimuli are suddenly altered. Both effects are likely to be important for animals evaluating signals composed of repetitions of single signal elements. Third, the precedence effect is strongly affected by other characteristics of signals besides their relative timing. Some of these other characteristics, in particular signal duration and frequency, as well as spatial separation, are likely to vary between populations and species, which may result in corresponding variation in the parameters and general importance of the precedence effect.

## Conclusion

The precedence effect is widespread in animals and is an important mechanism for sound localization in complex environments. In humans, this is particularly important in indoor, reverberant environments. In nonhuman animals, echo suppression may also be an important function of the precedence effect, although the adaptive significance of precedence effects and their relative importance in various auditory perception and processing tasks is poorly understood in most species. One potentially important function of the precedence effect is to facilitate localization of a signaler in the midst of multiple other individuals signaling in close temporal proximity. The precedence effect may therefore play an important role in sexual selection resulting in receiver preferences for leading signals, although in only a few cases has it been confirmed that the precedence effect is indeed the mechanism responsible for these preferences.

## Definition

A type of grip formally defined as involving the tips of the thumb and finger(s) and used by some primates for precise handling of objects of different size and shape.

## Anatomical, Mechanical, and Behavioral Definitions of Precision Grip

Hands capable of grasping have been central to our evolutionary success and define the order Primates. More than almost any other mammal, primates engage the world with their hands. Primates explore their environment with their hands.

Gripping branches during movement, collecting food, handling small objects and in some cases tools, and interacting socially with peers are all behaviors that involve the hands. With dexterous hands capable of prehensility and opposability (see ► [“Opposable Thumb”](#) entry), we humans can achieve daily tasks allowing us to make a living, build buildings, and manufacture objects ranging from tools and clothing to fine pieces of art. One feature that makes the hands of at least some, but not all, primates remarkably useful is the ability to manipulate small objects between the tips of the digits, a behavior often referred to as a precision grip. However, the exact definition of a precision grip is elusive, therefore our ability to identify which primates can or cannot use such a grip remains limited. In this entry, we provide a strict definition of a precision grip (while also acknowledging the range of definitions used by others), allowing for what we hope is a clearer, less ambiguous, and more unifying description.

Early descriptions of hand dexterity and grips used by primates were provided by Darwin in 1872 in the *Descent of Man* and then later by prominent anatomists, particularly John Napier whose descriptions and definitions of hand grips are still in use today (see Lemelin and Schmitt (2016) for a review). Napier (1956, 1960) first formally described the range of dexterity, gripping abilities, and behavioral flexibility of the human hand, then turned his attention to those same abilities in nonhuman primates. His observations, particularly in humans, led to the establishment of definitions for two major types of grips: the *power grip* associated with the handling of large objects with the whole hand; gripping the handle of a hammer is a classic example (Fig. 1a), and the *precision grip* associated with the handling of small objects between the fleshy pads or pulp of the digits, especially of the first and second digits (thumb and index finger) (Fig. 1b).

The dichotomy between power and precision grips involves fundamental differences in forces applied to manipulate an object with one hand. According to Napier (1960: 648), “The precision grip is employed where delicacy and precision of movement are required; the application of muscular power being a secondary consideration. In

**Precision Grip, Fig. 1** Examples of power and a precision grips achieved by the human hand: (a) a power grip on a wooden dowel (note that the whole hand, including the palm, is engaged with the object); (b) a precision grip in which a small object is gripped between the fleshy pads of the thumb and index finger; (c) a precision grip on a tennis ball (note the fleshy pads of the fingers facing that of the

thumb, and the palm does not contact the ball); (d) a power grip while opening a jar lid (note that the palm is in contact with the lid); (e) a precision grip used once the lid is loosened and the lid can be easily unscrewed (note the fleshy pads of the fingers facing that of the thumb, and the palm does not contact the lid)

contrast, the dominant characteristic of the power grip is the application of force; with delicacy and precision being of secondary importance.” Landsmeer (1962) picked up on this mechanical definition by classifying power and precision grips by the presence or absence of a “static” phase. While a power grip has a static phase (essentially holding the object tightly on the palm with motion of the whole hand and little

motion of the fingers), a precision grip lacks one (only movement of the fingertips associated with manipulation are involved).

The contrast between “delicacy and power” or “statics and movement” is at the heart of the definitions of precision and power grips. But to observe and classify grips effectively, it is also necessary to define grips by the underlying anatomy and the motions of the digits and at joints of

the hand, especially once an object is grasped. Therefore, Napier (1956: 903) says that the human precision grip is achieved when an “object may be pinched between the flexor aspects of the fingers and the opposing thumb” and the power grip when an “object may be held in a clamp formed by the partly flexed fingers and the palm, counter pressure by the thumb lying more or less in the plane of the palm” (Fig. 1a). Typically, a precision grip is most often illustrated as someone holding a small object between the fleshy pad or pulp at the tips of the thumb and index finger (Fig. 1b). However, as the object gets larger and the distance between thumb and index finger gets wider, the two grips look much more similar to each another, as when we hold a ball (Fig. 1c). This grip is often confused with a power grip but does not involve the palm.

The ways power and precision grips can be used as part of a single task can be illustrated by opening a jar with a lid. As pointed by Napier (1956), the palm is often first pressed against the lid using a power grip hand posture (Fig. 1d). As the lid becomes looser, a precision grip involving the tips of all fingers and the opposed thumb can be used to rotate and remove the lid (Fig. 1e).

Expressed in this way, the precision grip and the ability to rotate the thumb to face the index finger are linked since when holding a small object or rotating a lid, the pulp of the thumb and index finger must face each other. Therefore, it can be argued that only those primates that have a thumb capable of opposability (see ► [“Opposable Thumb”](#) entry for the distinction between an opposable thumb and opposability) should be able to achieve a true precision grip. But is this the case? To answer this, one must examine the abilities of nonhuman primates to achieve precision grips.

Numerous studies have described grip patterns in strepsirrhines (a primate group that includes lemurs, galagos, and lorises), tarsiers (small nocturnal primates from South East Asia), platyrrhines (monkeys from Central and South America), Old World monkeys (monkeys from Africa and Asia), and apes (see Fragarzy and Crast (2016) for a thorough review). Bishop (1964) conducted one of the most exhaustive

studies of strepsirrhine hand use and found little evidence of anything that could be called a proper precision grip. When a lemur grabs a food object, it gathers it up with the palmar surface of the digits, then presses it onto the palm (or sometimes smashes it with the palm first and then gathers it with the digits). Occasionally, galagos use a grip like the one we use on a jar lid, with the thumb opposed to the fingers, to grasp a grape. Bishop acknowledged that “One may apply Napier’s terminology and say these ‘precision grips’ differ from ‘power grips’ of locomotion” (Bishop 1964: 205). However, it is more accurate to say that very few of these grips truly qualify as precision grips, a point Bishop (1964) elaborated on.

There remains considerable debate about whether monkeys and apes can produce precision grips (see Pouydebat et al. 2009 and Marzke and Pouydebat 2009). However, following a strict definition of precision grip, monkeys and non-human apes do not produce true precision grips but rather produce what might be called “precise grips.” Pouydebat et al. (2009) argued that macaques and baboons achieve what might effectively be called precision grips because they can bring the pulp of the thumb and that of the index finger together. This is accomplished in part by virtue of their short index finger relative to the thumb. But to bring those digits together, they must rotate the thumb and generate acute flexion of the thumb and index finger in order to achieve pulp-to-pulp contact (Macfarlane and Graziano 2009). Capuchin monkeys (medium-sized platyrrhines with prehensile tails) also have thumb and index finger lengths that allow for pulp-to-pulp contact but like Old World Monkeys must flex their index finger and thumb to achieve this contact (Spinozzi et al. 2007; Macfarlane and Graziano 2009; Pouydebat et al. 2009). This kind of a grip for handling small objects seen in some New and Old World monkeys is required because their thumbs are incapable of true opposability comparable to that of humans (see ► [“Opposable Thumb”](#) entry). Chimpanzees and other non-human apes use similar contortions to achieve pad-to-pad contact and mostly handle objects between the thumb and the side of the index finger

(Christel 1993 and Frigaszy and Crast 2016 provide an excellent review). Napier (1960) showed that chimpanzees could occasionally handle a small object between the pulp of the thumb and index finger but could not produce a true precision grips because of the relative shortness of their thumbs. Gibbons are similarly incapable of producing precision grips because of their very long index finger relative to the thumb. Most often, gibbons grasp small objects between the pulp of the thumb and the side of the index finger (Christel 1993).

Clearly, only humans and a few monkeys are capable of pulp-to-pulp contact between the thumb and index finger, and they achieve this in different ways. Other primates do handle objects between portions of the thumb and index finger without pulp-to-pulp contact. This raises the question of what to call such grips. Pouydebat et al. (2009), Spinozzi et al. (2007), and Macfarlane and Graziano (2009) examined apes and other primates and classified many grips they observed as precision grips. These include grips that involved the thumb and multiple fingers, grips between the thumb and side of the index finger, and grips between the edges of any adjacent digits. These thumb to lateral edge grips (pad-to-side grips of Macfarlane and Graziano 2009) and “scissor grips” (between fingers grip of Macfarlane and Graziano 2009) may count as “precise” in a mechanical sense, because they allow an animal to hold a small object with delicacy and limited muscle force, thus meeting one of Napier’s (1960) definitions. They are clearly important and effective, but they do not meet a strict definition of precision grip.

## Conclusion

The precision grip, which has its ultimate form in humans, allows the handling of small objects between the pulp (fleshy pad) of the digits. In its strictest sense, a precision grip involves the pulp of the thumb and index finger and is linked with the presence of a thumb capable of true opposability. In that context, this is a type of grip used habitually and effectively only by humans. But a

precision grip may also be achieved in primates with relatively long thumbs or short index fingers (or a combination of both) that are both capable of acute flexion to bring the fleshy pads or pulp together. Broadening further, a “precise” grip can be achieved when an animal holds an object by the tips of its fingers, pinching a small object between the tip of the thumb and side of the index finger, or between two adjacent fingers (scissor grip). Although here we advocate a strict anatomical- and movement-based definition like that first articulated by John Napier (1956, 1960), we acknowledge that the term precision grip has been treated as malleable and readers must examine any work critically to be clear on what definition the authors are using.

Nidifugous

## The Precocial/Altricial Spectrum

At the moment of hatching or birth, animal species differ in their degree of development. While precocial species are able to move in the environment and feed autonomously at the onset of life, altricial species depend on parental care for feeding and cannot navigate the environment. Precocial animals are born with the eyes open and have down, altricial animals are born with eyes closed and little or no down.

Precocial species whose neonates leave the nest soon after hatching are called nidifugous, while species that remain in the nest for much of their development are referred to as nidicolous. Notions based on nest attendance partially dissociate with that of precocial and altricial, for some motor developed birds remain in the nest even if capable of locomotion, when the location of the nest prevents exploration.

Based on maturation of the neonates and behavior, the precocial-altricial spectrum ranges along a continuum that has been particularly well explored in birds (Starck and Ricklefs 1998). Chicks of megapodes (a family of Galliforms) are known as superprecocial, because they are fully independent from their parents and, in some cases, are able to fly from the first day of life. Most galliforms (e.g., chickens, mallards, quails, and pheasants) are precocial and can feed and move independently, leaving the nest 2–3 days after hatching. In these species, though, chicks follow their parents, and parental care is important for thermoregulation and for directing appropriate behavioral responses. Semiprecocial birds, such as the young of many seabirds (e.g., gulls, alcids, and terns), are born with relatively less developed locomotor activity and depend on their parents for feeding. After few days after hatching, chicks leave the nest to hide but return to be fed by their parents. Among mammals, precocial species are found for instance among ungulates (e.g., antelopes, sheep, horses, cows, deer), guinea pigs, and hare. In some of these species, neonates are able to follow the mother few hours after birth (Rosenblatt 2010). Species whose neonates remain in the nest for much or all of their development, such as passerines and psittacines (parrots), are altricial and nidicolous.

## Evolution of Developmental Modes

Precocial and altricial modes of development have important connections with different aspects of the ecology of a species. Precocial animals are typically exposed to high predation rate, such as chicks born in nests located on the ground or

young ungulates that forage in exposed locations. A strategy of altricial species to reduce predation is laying eggs in inaccessible locations. Most of the losses of precocial species are concentrated in the early growth period. This has suggested the hypothesis that the precocial mode of development has evolved as an adaptive response to high predation on relatively vulnerable juveniles (Williams 1966). In line with this idea, many precocial species show filial imprinting, a fast learning mechanism that mediates affiliative responses towards the first conspicuous objects that the neonates experience, and exhibit spontaneous, unlearned behaviors that enable them to effectively respond to the environment even in the absence of specific experience.

### Instinct and Predispositions

At the onset of life, precocious knowledge can help unexperienced individuals in making correct predictions, deciding whether to approach or avoid specific objects and in coping with novel situations (Versace and Vallortigara 2015).

In the first days of life, many precocial species exhibit filial imprinting, a fast and specialized learning mechanism that enables the neonates to learn the features of the first conspicuous, moving objects experienced after a brief exposure. In the wild, filial imprinting produces strong affiliative responses of the young towards their mother. It appears that, in the absence of previous experience, neonates “know” that they will have a *mother*, and they should respond by following her, and that they are equipped to learn the individual details of their mother from the environment. The mechanism of imprinting, made popular by the ethologist Konrad Lorenz (1937), lies hence at the interface between unlearned and learned knowledge. In the fields of ethology, animal and developmental psychology, precocial species have been used to investigate the presence of instincts/innate behavior (see Bateson 2017 for a critical approach to the notion of innate; and Burghardt 1973 for a historical review of this concept that traces back to Darwin), predispositions (Bateson 2017; Johnson and Horn 1988), and core

knowledge systems (Spelke 2000). These notions refer to behaviors and capacities that are not acquired during the ontogenetic development through learning but emerge without specific experience, as *a priori* knowledge. Interspecific differences in spontaneous behaviors provide support of nativist theories of knowledge.

One approach to investigate the presence of spontaneous capabilities is based on deprivation experiments/studies and controlled rearing studies, in which experimenters exclude or manipulate exposure to specific stimuli until the moment of test. If a species shows consistent responses to a stimulus (e.g., a preference for a face configuration vs. a control stimulus) before individuals had any experience that could have influenced their responses (e.g., before having experienced any face-like pattern), then it is possible to argue for the existence of some knowledge on how to respond to that stimulus. This approach has several practical and ethical limitation for altricial species, which have to be nurtured for extended periods before being tested, but is more suitable for precocial species. For instance, it is easy to keep newly hatched domestic chicks in darkness before testing their spontaneous visual preferences (reviewed in Di Giorgio et al. 2016; Versace and Vallortigara 2015), or exposing them to controlled imprinting stimuli to investigate their capacity of learning and memory (Bateson 1966; Bolhuis 1991). In fact, since the late nineteenth century (Andrew 1991; Bateson 2017) many studies on the existence and content of precocious knowledge have been conducted on avian precocial species, such as young domestic chickens, goslings, and ducklings, in different domains and sensory modalities. As for acoustic modality, Gottlieb (1968) showed that, in ducks, embryonic auditory experience with the own calls produces species-specific preferences for acoustic stimuli. In this species, the little experience gained by the embryo is sufficient to orient subsequent approaching responses to calls of conspecific. As for visual stimuli, a wide range of experiments has identified preferences of newly hatched chicks to approach specific colors, size, shapes, as well as configurations of static and dynamic stimuli (reviewed in Di Giorgio et al. 2016;

Versace and Vallortigara 2015), and unlearned knowledge about the properties of objects, number, and geometry has been shown (Vallortigara 2012). The advantages of precocial models is particularly clear for the study of social predispositions, given that altricial species cannot be deprived of social care. Studies on domestic chicks have identified unlearned preferences for static and dynamic stimuli associated with animate, living beings, which have been subsequently observed in altricial species too, including human beings (reviewed in Di Giorgio et al. 2016). The co-occurrence of early preferences for face-like stimuli, biological motion, and self-propelled objects initially investigated in social precocial species has suggested the presence of a core knowledge system dedicated to social responses (Di Giorgio et al. 2016).

## Conclusion

At birth, animal species can be classified along the precocial/altricial continuum, according to their developmental maturity and behavioral independence from parents. Precocial species feed and navigate the environment autonomously, altricial species are immature for locomotion and are fed by the parents. Investigation of the mode of development is important both to clarify the evolutionary pathways that have led to the ecology and adaptation of different species, and as a tool to shed light into the origins of knowledge. Ease of experimental manipulation made precocial birds elective subjects for the study of predisposed behaviors.

## Introduction

Predation is one of the strongest evolutionary forces in the animal kingdom. The need to catch food influences the ecology, morphology, and behavior of predators and prey alike. As a consequence, predation risk has not only a stark effect on the single individual but further shapes food webs and whole ecosystems. Predator-prey interactions can be understood as an arms race: Over evolutionary time spans, predators developed a multitude of hunting strategies to catch prey, which in turn developed better and more sophisticated antipredator strategies. Such arms races are indeed the cause of many extraordinary color patterns and morphological features as well as fascinating behaviors observed in nature. In the following we will elucidate these diverse adaptations of predators and prey, followed by a short overview on the evolutionary consequences of predation risk on shaping complex social organizations of predators and prey at the same time.

## Adaptations of Predators

Predators evolved multifarious morphological and behavioral adaptations that increase their chances to successfully hunt prey. Many predators are active hunters that search for prey animals. Once spotted, these prey items might be chased until they are caught. Such active hunters are characterized by well-developed muscles which support high-speed pursuits, excellent sensory capabilities, and a huge repertoire of stealth and stalking techniques. It is therefore

not surprising that the fastest animals on land, water, and in the air are all highly specialized predators. The peregrine falcon (*Falco peregrinus*), for example, is the fastest animal alive, with a diving speed of up to 389 km/h. But predator's adaptations are not limited to increasing the attacker's speed. Nocturnal predators, such as the African wildcat (*Felis lybica*), have specialist eyesight and large pupils to see even the faintest light during darkness, while sharks are able to sense the electric field of other animals, allowing them to spot prey which is cryptic or hidden in the sand.

By contrast, ambush predators don't rely only on strength or speed; instead they hide and wait until prey is close enough before starting an attack. A common house cat sitting motionless in front of a mousehole is a prominent example of such hunting tactic. To reduce their visibility, many ambush predators, such as the cougar (*Puma concolor*) or the devil scorpionfish (*Inimicus filamentosus*), bear camouflage color patterns that allow them to stay unnoticed by prey until striking the attack. Orchid mantis (*Hymenopus coronatus*), for example, resemble orchid flowers in color. Insects that visit this apparent nectar source are attacked and killed. Ambush hunting is less energy-demanding than active searching for prey. However, the chance to meet a prey item is reduced. To increase such chances, some ambush hunters evolved morphological or behavioral features attracting prey animals, a phenomenon termed "aggressive mimicry" (Jamie 2017). For example, alligator snapping turtles possess a modified tongue, which resembles a worm. Hiding on the muddy bottom of a lake, they open their mouth and move their worm like tongue. Small fishes get attracted by this lure and swim directly into the mouth of the turtle. A further example is Livingston's cichlid fish (*Nimbochromis livingstonii*), a predator showing sophisticated adaptations in behavior and color. To attract its prey items, it feigns death and mimics a rotting fish. Other fishes that approach this potential snack are attacked and eaten. Finally, some ambush hunters like spiders or ant lions evolved sophisticated traps to catch bypassing prey.

Many predators like tigers, sharks, or birds of prey hunt alone. Such solitary hunting has the benefit that the catch does not have to be shared between several individuals. Furthermore, a single hunter is more difficult to be detected when approaching prey animals than a group of predators. However, compared to group hunting species, the success rate of solitary hunters is lower, and they often face difficulties to bring down large prey items. Such problems might be overcome if individuals gather together and hunt as a group (Davies et al. 2012). Indeed, group hunting evolved frequently throughout the animal kingdom, exemplified in packs of wolves or pods of killer whales. While many of such group hunting species did not evolve coordinated hunting strategies, others show highly coordinated behaviors. For example, lions (*Panthera leo*) form hunting coalitions that are more successful than single individual's hunting. Forming such hunting groups requires coordinated behaviors, advanced communication, and very often division of labor between group members. In such highly derived group hunting species, sharing the catch among group members is often based on social hierarchies, which are based on dominance ranks, age, or sex. Sharing the catch is usually neither fair nor equal. Thus, more dominant individuals are often more strongly benefitting from group hunting, while it might pay off for low-ranked individuals to hunt alone.

### Adaptations of Prey

While a predator that is unsuccessful in capturing a prey item usually only loses a meal, a prey animal that fails parrying an attack will lose its life. Consequently, prey animals evolved a fascinating array of morphological, physiological, cognitive, and behavioral features, lowering their predation risk and increasing survival chances. Such antipredator adaptations can be categorized broadly into strategies to (1) avoid encountering and detection, (2) escape an attack, and (3) deter predators (Godin 1999).

### Strategies to Avoid Encountering and Detection

Many prey animals avoid predators spatially or temporally. For example, in the presence of large fish predators, small fishes like guppies (*Poecilia reticulata*) might move to shallow parts of the pond or brook, as large predators are not able to follow them there. Other prey animals might switch their daily activity, hiding during the daytime and foraging during the night. Nocturnal migration to the water column by zooplankton is a fascinating example of such temporal avoidance of predators. However, if the possibilities to avoid predators in space or time are limited, alternative strategies to reduce the risk of being detected and identified as potential prey are needed. A straightforward strategy to reduce the risk of being detected is by seeking a shelter or by reducing body activity to a minimum until the risk is over. Indeed, some prey species reduce their heart rate to cease their activity and remain immobile when being approached by a predator. Detection risk might further be lowered through camouflaging and masquerading. Here, prey coloration and/or morphology resembles the environmental background of the habitat or an uninteresting object such as leaves or twigs to increase the chances of staying unnoticed by predators (Ruxton et al. 2004). Such visual features might be permanent or highly flexible and readily adjusted to the respective environment. Leaf (Phylliidae) or stick insects (Phasmatodea) are prominent examples of permanent camouflage, whereas chameleons (Chamaeleonidae) and octopuses (Octopoda) use a flexible strategy to avoid predators by readily changing skin color to match the surrounding environment. In some cases, harmless and nontoxic species mimic other species that are better able to defend themselves or are poisonous. Harmless hoverflies (Syrphidae) resembling aggressive wasp and bee species (Batesian Hymenoptera) are famous examples for such mimicry (Ruxton et al. 2004).

### Strategies to Escape an Attack

Once being detected by a predator, fleeing is the most common strategy of prey animals to avoid being eaten (Godin 1999). A successful flight by

prey animals consists of an adequate timing to initiate the flight and a high-speed flight trajectory which leads into a safe area. Further, prey species relying on escape often show special adaptations. Many predator fish species, for example, are not able to ascend quickly in the water column, as their swim bladder will burst due to fast changes in pressure. However, physostomous fishes like herring, which are a common prey for many aquatic predators, possess an open swim bladder that is connected to their gut. These fishes can reduce pressure by excreting gas bubbles. This allows them to ascend quickly and thus escape predator attacks (Blaxter 1985).

To successfully escape an attack, it is important to spot the predator as soon as possible. Here, living in a group is highly beneficial. Groups detect predators faster than single individuals do, a phenomenon termed the *many eyes effect*. By joining forces, the overall vigilance time of a group might even increase without compromising time for other behaviors such as feeding and mating (Krause and Ruxton 2002). Furthermore, group living in itself is already a very effective antipredator strategy. Group-living species such as the gigantic flocks of snow geese and the herds of migrating wildebeest in the Serengeti are protected from predators because their sheer numbers confuse and repel predators which are not able to single out lone individuals. Finally, the dilution effect postulates that living in a group simply reduces the risk of each single individual to be the target of the predator (Krause and Ruxton 2002).

### Strategies to Deter Predators

Prey can deter predators using defensive adaptations such as toxicity, spines, or defensive behaviors. Often, toxic prey species evolved signals that are associated with the unprofitability to potential predators. These bright and conspicuous warning colors have been coined “aposematism” (Ruxton et al. 2004). The tropical poison frogs (Dendrobatidae), for example, are brightly colored to advertise their toxicity to potential predators (Santos et al. 2003).

Many prey animals show aggressive defense behaviors toward the predator. These are

especially effective in group-living species which defend the group jointly (Krause and Ruxton 2002). For example, pairs of crows will join together to chase away hawks from their breeding sites, and herds of buffalos will aggressively confront lions together.

### Impact of Predation Risk on Higher Organizational Levels

Predation risk can shape whole populations either indirectly (as explained above in *Adaptions of prey*) or directly through the consumption of prey animals by predators. Direct predation has a negative effect on survival and longevity of individuals and therefore selects individuals which are able to avoid predation risk and thus pass their genes to the next generation. This has a major influence on the way how individuals within a species interact with each other, determining the social structure and mating system of whole populations. For example, predation risk mediates the evolution of highly social societies where individuals cooperate with each other to raise their young (Groenewoud et al. 2016).

Predation risk also affects behaviors and survival of individuals which have not been directly exposed to predators but “inherited” information about predators from their parents. These so-called nongenetic parental effects are widespread in the animal kingdom and enable the transmission of information about local predation risk to the next generation. For example, the common water flea (*Daphnia pulex*) develops a thick armour as a protection from predators. Interestingly, offspring from mothers that experienced predators develop thicker armour irrespective of whether they have experienced predators themselves (Agrawal et al. 1999). In mammals and birds, predation risk as experienced by mothers can alter the stress responsiveness of offspring via maternal hormones through the milk in mammals or through hormones deposited inside eggs in birds (Sheriff and Love 2013).

Ultimately, reproductive barriers between species can be removed or created depending on predation risk. The ability of prey species to

adapt to predators and to expand into habitats containing new predators greatly influences how successful species disperse and thus influences the potential for speciation to occur (Siepielski and Beaulieu 2017).

## Conclusion

The constant struggle to survive is the major evolutionary force in the animal kingdom, leading to an arms race between predators and prey. Predation risk influences individual behaviors, population dynamics, and ultimately the evolution of animal social societies. Certainly, humans are not excluded from this struggle, and human sociality has been shaped just like any other animal sociality by the need to survive and catch food (Hart and Sussman 2008). Only by understanding the evolutionary forces shaped by the struggle to survive we are able to fully appreciate the development of the rich and interesting facets of animal behaviors and animal sociality.

## Predator

Neha

Laboratory of Molecular Ecology, Department of Botany, Banaras Hindu University, Varanasi, India

## Definition

An organism that captures and survives by feeding on other organisms is called as predator.

## Introduction

The predator gains energy to sustain life and encourage its reproduction on the cost of an organism being eaten, the prey. Predators sit at the top of the food chain and consume its prey perched one trophic level below, which in return

eats plants, the basis of the ecosystem (Hairston et al. 1960). Predator plays a very crucial role in framing the ecosystem structure and function. Predator-prey interactions change the community structure, arbitrate trophic cascades, and influence biodiversity and species invasions. Moreover, the prey population dynamics can be controlled by predators by affecting features such as survival, behavior, growth, size, structure, and distribution over an area. Besides animals, carnivorous/insectivore plants like the Venus fly trap and pitcher plant which feed on insects also show predation. These plant species grow in nitrogen-deficient soil. Pitcher plants seize their prey in a cavity containing liquid with digestive enzymes; in contrast, the Venus fly trap catches an insect within the leaf lobes, and the insect is sealed inside. The required nutrients are absorbed by the plants from these insects. Microorganisms like protozoa and bacteria also ingest their prey through phagocytosis. These microbes play very crucial role in balancing population size in microbial communities, which in turn stimulate the diversity of microbes and provide a stable community structure. Predators not only involve the fanged animal that consumes primary consumers but also include organism feeding on those organism which are smaller or of the similar size or even larger like grazing animals whether the grazed organisms can be plankton or mats of microbes (Bengtson 2002). Sometimes seed consumption is also considered as predation as seeds are thought as organisms. Under ideal conditions, seeds emerge to become a complete plant, although, consuming a seed terminate the plant before it can originate, making seed consumption an example of predation (Janzen 1971). Seed predators are limited mainly to mammals, birds, and insects and are present in nearly all terrestrial ecosystems (Hulme and Benkman 2002). Likewise, consumption of egg is also considered in the category of predation as it also causes the death of an entire organism before its growth (Nilsson et al. 1985). Egg predators comprise of some snakes, birds, and mammals, for example, red fox as they opportunistically eat the egg (Hanssen and Erikstad 2013). There are some nematophagous fungi that feed on nematodes which use either active traps in

the form of constricting rings or passive traps with adhesive hyphal structures (Primer 1964). There are a number of microbes like bacteria and protozoa that prey on other microorganisms and hence play very significant role in regulating population sizes in these microbial communities promoting diversity of microbes and stable community structure (Velicer and Mendes-Soares 2009; Stevens 2010a).

Adaptations which make predator highly specialized for killing the prey include sharp teeth, claws or jaws to hold the prey, and venom. Moreover, predators are adapted with highly specialized acute senses such as vision, hearing, or smell. Other adaptations include stealth and aggressive mimicry that improve hunting more efficient. Predation has a powerful selective effect on prey, and the prey develops antipredator adaptations such as warning coloration, alarm calls and other signals, camouflage, mimicry of well-defended species, defensive spines, chemicals, etc.

## Classification of Predators

Predators can be classified in two ways: (1) taxonomical classification and (2) functional classification (Begon et al. 2006). Taxonomical classification consists of carnivores consuming plant-eating herbivores. The functional classification includes four types of predators: true predators, grazers, parasites, and parasitoids. True predators more or less kill their prey right after attacking them. Some examples of true predators are most of the carnivorous animals like lion, tiger, eagles, and snake and some carnivorous plants such as pitcher plant and so are seed-eating rodents and ants, plankton-consuming aquatic animal, and so on. Grazers are organisms that partially consume their prey and are hardly lethal. It attacks large number of organism (prey) in their life span. Grazing differs from true predation in the way that the organism being grazed is not killed. The vertebrate herbivores like cattle and sheep are the most common examples of grazers. Parasites feed on parts of their prey (their host) and are rarely lethal in short span of time. Examples of parasites are tapeworm, liver flukes, many

pathogenic bacteria, fungi viruses, etc. Parasitoids are the organism that lives in association with their host bodies where they feed, grow, and ultimately kill their host.

## **Adaptations for Predation**

Predators are key driving factors in structuring ecological communities and processes. A predator's utmost important task is to find or search, chase, and kill its prey to feed. Once predator locates its prey, it must evaluate either to pursue it or to wait for a better option. If the prey organisms are large in number and are mobile, in that case, the sit-and-wait method is the most appropriate method of foraging (Bell 2012). If preys are inactive and scantily distributed, in that case, foraging requires more energy. Predators catch their prey either by pursuing potential prey or by ambushing them. Predation affects the fitness of prey and predators both. To survive and reproduce, organisms must both feed and protect themselves from being eaten. Genetically determined traits that improve an organism's ability to sustain and reproduce will be transferred to next generation. Traits related with improved predation for predators and escaping predation for prey inclined to be positively selected by natural selection. Predators exhibit a variety of adaptations like sharp teeth, claws, speed, and venom that strengthen their capability to catch food. They also own extremely vital sense organs which help them to detect potential prey. To sustain life, predators must be capable to outsmart their prey and use their acute senses, as well as evolved physical adaptations such as sharp teeth and claws, with various hunting tactics.

### **Senses**

Predators have fine sense of smell, vision, and hearing which tend to be very curious regarding their surroundings.

#### **Vision**

Predators have forward-facing eyes placed on the front of their head providing them three-dimensional binocular visions, whereas eyes of the prey are placed on the sides of their head.

Forward-facing eyes allow predator a more restricted view of the surrounding than prey and make it easier to determine distance and see each and every detail from far distance. Apart from binocular vision, predators also have big eyes which help them to pick up light signals easily and are therefore able to spot quick movements.

#### **Smell**

While predators depend greatly on their sight to locate the prey, they also possess a well evolved sense of smell. Almost all animals release some chemicals into the environment, which are by-products of metabolism. Many predators have the capability to detect these chemicals to find the animals releasing them (Conover 2007). There are some animals such as fox, wolves, and coyote that rely on their sense of smell rather than their vision. These animals possess longer snout which has chemically sensitive cells. For example, foxes are very sensitive to smell such that they can smell their prey lying even two feet under the soil or snow. Reptiles also bear acute sense of smell and can detect smells in very different manner. They stick out their tongues to sense smell in the air. A special organ, Jacobson's organ, present on top of the reptiles mouth, allows them to smell chemicals present in the air and detect food present nearby.

#### **Hearing**

Predatory animals have a very sharp sense of hearing. They have a special feature of rotating their ears forward and backward to locate the direction from where the sound is coming. The most common example is the bat, which has very sensitive hearing. They have large ears as their primary means of finding prey. Bats produce high-pitched ultrasonic sound waves which are above the upper limit of human hearing. Whenever these sound waves hit something it produces echo. These echoes are heard by bats and they can locate the object. This process of echolocation is used by bats to find their prey. Dolphins also echolocate their prey.

### **Hunting Strategies**

Predators have developed different methods of locating and killing their prey. Some of these

strategies include stalking, chasing, sit and wait, etc.

### Stalking

Predatory animals that stalk and follow their prey have very well-developed features which assure that they are able to sneak on their prey undetected. For example, soft padded and retractable paws of cats help them to walk silently. Animals stalking for their prey must have quick reflexes to ensure that their prey is caught.

### Sit and Wait

This sit-and-wait strategy requires less energy. The animal that employs this strategy to kill its prey generally has some form of camouflage. They blend in with their surroundings to avoid detection and wait for their prey. The sit-and-wait method of foraging is suitable if preys are densely populated and mobile, and predators require less energy.

### Group Hunting

Some predators hunt their prey in groups. The advantage of group hunting is that the large number of predators kills prey animals much larger than themselves. For example, this type of hunting strategy is often seen in wolf packs which have very systematic way of hunting.

### Physical Adaptation

Apart from various hunting strategies, the predatory animals have adapted different traits such as sharp teeth, jaws, claws, and venom that increase their capability to catch food.

### Teeth and Claws

Predatory animals possess long, sharp claws and teeth particularly for tearing, shearing, and cutting the prey. Predatory birds such as hawks, eagles, and falcons have special long curved claws called talons, which help these birds to grasp their prey easily.

### Jaws

Jaws of predatory animals are very strong which enables them to hold and kill the prey as well as tear them to feed themselves. The jaws move up and down which enables the predator to cut

through flesh. Snake's jaw is adapted in order to swallow whole prey.

### Special Features

Many predatory animals possess some specialized body parts that help them to catch and consume their food. Frogs bear long tongues that help them to capture insects, and long sharp beak of great blue herons helps them to catch fish. Likewise, otters have webbed feet and distinctive oils which make them waterproof and help them swim easily and catch food. These specialized characters have been adapted according to environment and feeding conditions.

### Intelligence

Predatory animals are more intelligent than the prey. Their intelligence helps them to outsmart their prey. Crows and raven are among the most intelligent birds. They can even copy various sound such as cat meows and whistles.

## Antipredator Adaptation

To avoid predation, prey animals must escape from the predators to survive. The aim of feeding is to locate and capture food without being caught by the other animal. Lots of prey animals have developed and adapted to protect themselves from predators: camouflage, senses, warning signals, different types of defensive weapons like chemical defense, behavioral adaptations like bluffing, hiding, and living in groups. In order to survive, prey animals use these kinds of adaptation against predators.

## Coevolution of Predators

Predator-prey interactions are very prevalent in nature. Predator and prey are adapted in such a way that they can counter each other. For example, bats uses echolocation system to detect their prey, and in return, insects have adapted various defenses to counter bats including the capability to hear the echolocation call. Likewise the land predators such as wolves have evolved long limbs to run after prey. These types of adaptation have

been characterized as an evolutionary arms race, an example of the coevolution of two species. When a predator pursues a potential prey, the predator is chasing its food, and the prey is running to save its life. If in any case predators fail to catch the prey, it remains starving, but as a consequence of this interaction, it will not suffer a large decline in fitness. In contrary, if the prey is captured by the predator, the seized animal loses opportunity to reproduce in the future. This “life-dinner principle” arranges an evolutionary arms race between the two species (Dawkins and Krebs 1979). In this evolutionary race, the prey undergoes strong selective pressure to evolve better to prevent predation. At the same time, for survival and reproduction, predators must capture sufficient food, and they are put through selective pressure for traits that allow them to hunt successfully. Because of this arms race, the prey has been capable to avoid capture, and predators become able to catch prey efficiently. In some of the examples explained so far, some of the prey species possess bright coloration. Such aposematic coloration helps prey animals from predation by signalling predators that the brightly colored individual is toxic (Stevens 2010a). All the vivid colorations exhibited by the species are not truly toxic. In some species patterns and colors have evolved to mimic those of toxic species. Batesian mimicry is one of such examples, which includes the exceptional polymorphic *Papilio dardonus* swallowtail butterfly in Southern Africa and Madagascar (Salvato 1997). Female of this species presents in a wide variety of physical appearances among which most of them mimic distasteful species of the *Danaus* and *Amauris* genera with which they co-occur.

## Dynamics of Predation

Population of species is not everlasting. The number of individuals in a population keeps changing from one time period to the next. Such fluctuations are regulated by the resource availability. When the resources are limited, population declined as organism competed for the limited resources. This process of bottom-up control

helped to regulate the population about carrying capacity. Recently, scientist has found that predator population can affect the prey population size by acting as top-down control. If predators are not present, the population of species grows exponentially till it reaches the carrying capacity of the environment (Neal and Dick 2004). Predators often control the growth of prey species both by consuming them and by changing their behavior (Nelson et al. 2004). Actually, the interaction between these two patterns of population control efforts together to operate changes in population over the time. Some other factors like parasite and disease can further influence the population dynamics.

Change in population occurs in species that encounter large cyclic swings in the population size. These cycles occur simultaneously with population cycles of other species within the same location. The availability of food resources functions as bottom-up control that affects the size of population. Whenever the food is abundant and easily available, the population size will increase, and when the preferred food is scanty, the organism turns to undesirable food to prevent starvation. As a result, these organisms grow more slowly and reproduce less, and hence, the population declines. As the population of predator organisms increase in number, they put substantial pressure on prey populations and act as top-down control, pushing them to decline. Lotka-Volterra is a simple model that provides a useful tool to help population ecologists understand and determine the factors that affects the population dynamics and to predict population cycle (Stevens 2010). They have been particularly beneficial in understanding and predicting predator-prey population cycles. Although the models greatly simplify actual conditions, it demonstrates that under certain conditions, predator and prey populations can oscillate over time (Fig. 1).

## Role of Predators in Ecosystem

Predators play a very important role in the trophic cascades. They are connecting link between nutrient cycling. They can affect the genetic makeup,

**Predator, Fig. 1** Lotka-Volterra model: Predator and prey population cycle

morphology, physiology, and behavior of prey species. They regulate and control the population of the prey.

### Role in Food Chain

Predators are at the top of the food chain and they play an important role in linking the nutrient cycles in the ecosystem. In the absence of predators, herbivores began to overgraze many plant and grass species, hence, affecting the area's plant population. In a decisive study on the effects of predators on the environment, William Ripple and Robert Beschta (2009) of Oregon State University found that the presence of large predators is important in sustaining native plant communities in both upland and riparian (stream or river) settings because plants contribute to a wide range of "ecosystem services" such as floodplain functioning, soil development, and stream bank/channel stability.

### Selective Impact on Prey

Predators are very selective in choosing the prey species. Predation on larger prey often demands substantial threat to the predator and always demands a significant investment of energy. Accordingly, the predators always select the convenient prey, sick, young, and weak.

### Biodiversity Management by Predators

Biodiversity of different communities may be increased by predators. By preventing single species from becoming dominant, predators manage the biodiversity. Such predators are

called keystone species and can have acute effect in balancing the organisms in a particular ecosystem (Bond 2012). Introducing or removing this predator by changing its population density can result in drastic cascading effects on the equilibrium of many other populations in the ecosystem. For example, in grassland ecosystem, grazers may control the single dominant species from becoming most influential (Botkin and Keller 2003).

### Conclusions

Predators are important in maintaining a healthy ecosystem. Predators are important not only because they create biodiversity but also because they indicate biodiversity. In addition to regulating natural systems as described above, predators (especially large predators) serve as a measure of the health of communities around them. Top predators are associated with high biodiversity value because they are sensitive to ecosystem dysfunctions, such as pollution and habitats.

## Synonyms

[Antipredator strategies](#)

## Definition

A set of traits and mechanisms by which prey avoid being detected, recognized, subjugated, or ultimately consumed by their predators.

## Introduction

Most organisms are at risk from predation. For this reason, many species have evolved certain traits or strategies that confer different degrees of protection. Such traits and strategies can be physical (morphological), chemical, or behavioral and can be exhibited by both individuals and groups. As a result, predator defenses are very diverse and are widespread across the animal kingdom. However, several key strategies have evolved separately in multiple groups of animals.

In order to classify and understand these defenses, we must first understand how animals fall prey to others. The process of predation can be thought of as a sequence, beginning with the detection of the prey by a potential predator, followed by its recognition as a suitable prey item, its subjugation and, finally, its consumption (Endler 1991). Animal defenses can intercept and disrupt this sequence at any stage, and many species possess defenses that act on several stages. From the prey's perspective, defenses that interrupt the process at the earliest stages, i.e., before the subjugation stage, may be particularly

valuable as they reduce the opportunity for injury or energy loss from fighting or escaping.

### Preventing Encounter and Detection: Avoiding the Issue

The first line of animal defenses includes those that prevent encounter or detection. Encounters can be avoided by prey being in low densities, so as to reduce the per capita probability of being found by a predator. Alternatively, prey

may try to create spatiotemporal separation from predators, by either avoiding areas inhabited by potential predators or using those areas at different times than the predators. Prey can also use hiding shelters (Fig. 1a) at known locations within their home ranges and may remember and use set escape routes. One extreme example comes from the Chuckwalla (*Sauromalus obesus*), a lizard that hides in rock crevices when threatened, and then inflates itself with air so it cannot be pulled out (Deban et al. 1994).

**Predator Defense, Fig. 1 Examples of animal defenses against predators.** (a) some animals use shelters or refuges within their home range; (b) many frog species avoid detection by displaying color patterns that match those of their background; (c) fish schools are an example of how some organisms move in groups to minimize the per capita risk of predation; (d) insects such as katydids avoid recognition by resembling inanimate objects, for example, leaves; (e-g), aposematic organisms display distinct color patterns that predators learn to associate with their unprofitability; (e) Burnet moths (family Zygaenidae) sequester cyanide compounds from their food plants, but are also capable to produce them de novo; (f) the granular poison frog (*Oophaga granulifera*) uses its vivid colors to warn predators about its possession of toxic skin secretions; (g)

coral snakes (genus *Micrurus*) serve as models to some harmless colubrid snakes, which gain protection from predators by mimicking the coral snakes' color patterns; (h) body inflation helps animals appear larger than they actually are and discourage attacks from predators, or can make subjugation more difficult; (i) weapons such as deer antlers may be used for purposes other than protection from predators, for example, during male-male competition; (j) eyespots in the wings of butterflies are thought to mimic vertebrate eyes and thus can startle predators, making them hesitate to attack; (k) the defensive secretions of poison frogs contain mostly alkaloids that act as neurotoxins; (l) blue tits (*Cyanistes caeruleus*), among other species of Paridae, produce mobbing calls when predators are nearby (Photos taken by B. Rojas)

Once the prey encounters a predator, then there are behavioral and morphological mechanisms aimed to hinder detection. Rabbits can, for example, “freeze” in response to an unexpected noise. Immobility can also be employed by anuran larvae in the presence of a larger carnivore tadpole, such as an odonate naiad or a water bug. This strategy works because many predators are motion-oriented and, thus, fail to detect static, unmoving, prey. This behavior can be coupled to traits such as cryptic coloration (see below), which act in concert to make it harder for predators to detect prey. Prey can also aggregate, for example, through synchronized hatching (insects, amphibians, reptiles), or the formation of schools (fish; Fig. 1b) or flocks (birds) whereby the per capita risk of predation is very low; this phenomenon is known as the dilution effect. One famous example comes from periodical cicadas: these true bugs, from the genus *Magicicada*, have 13- or 17-year life cycles. They spend the majority of their life feeding underground as larvae, and once every 13 or 17 years emerge simultaneously as adults to mate and lay eggs. The sheer number of cicadas during this emergence means that predators quickly become satiated and cannot eat more than a small proportion of the population (Williams and Simon 1995).

Among the morphological mechanisms to thwart detection, those related to prey coloration are probably the most well known. Cryptic prey, for example, resemble the background on which they rest (Fig. 1c), or exhibit disruptive coloration, which breaks the prey’s body outline (Stevens and Merilaita 2009). This can hide an animal’s distinctive shape and make it harder to distinguish. Because in most cases predators form a search image to look for prey, research has shown that cryptic prey benefit from being polymorphic. That is, from exhibiting variable color patterns within a population to minimize per capita predation risk, as this makes more difficult for predators to create an efficient search image and stick to it. Other forms of color-mediated concealment are *transparency* and *countershading*, both of which are commonly seen in marine organisms.

Transparency is widespread in pelagic (i.e., open water) species, in particular among small, free living organisms such as Ctenophora (or comb jellies), some Cnidaria (a group which includes jellyfish, sea pens, and hydra), and the larval stages of many crustaceans (Johnsen 2001). In countershading, animals have darker coloration on the top side of their bodies and lighter coloration underneath. As light usually hits objects from above, making them appear lighter on top and darker underneath, this form of coloration can mask this effect, making the animal’s body appear less three dimensional, and therefore harder to spot. In particular, countershading has been suggested to function in marine animals such as whales, sharks, and fish, as when viewed from above the darker coloration on the dorsal (top) side of the both will blend into the darker-appearing waters below. In contrast, a lighter ventral (underneath) side will stand out less against the light filtering down through the water when viewed from below. While a great many species show this form of coloration, experimental evidence for its effectiveness against predators is limited, and it has been suggested that other factors, such as protection from harmful UV rays or thermoregulation, may also explain this pattern (Rowland 2009).

### **Preventing or Aiding Recognition: It Is Not What You Think**

Once the prey has been detected, the predator needs to recognize it as an edible item worth attacking. At this stage, animals may benefit from imitating inanimate objects in their surroundings, a phenomenon termed *masquerade*. Stick insects, for instance, get their name from their extraordinary resemblance to sticks and twigs, praying mantises and some katydids also benefit from resembling green leaves (Fig. 1d), whereas some tropical toads look a lot like fallen leaves in the leaf litter, and the larvae of some lepidopterans look like bird droppings. Masquerade is often considered to fall between mimicry and crypsis, as it is often difficult to assess if a

predator has truly misidentified the prey as an object or has simply failed to notice it. However, true masquerade should remain effective across many different backgrounds (Skelhorn et al. 2010). In nature it is likely that many species use a combination of the two, for example, by closely matching the most common items in their environment.

*Aposematism* is another strategy related to prey recognition but, in this case, prey recognition is enhanced rather than hindered. Aposematic animals (Fig. 1e, f, g, k) employ warning signals, often conspicuous color markings, to inform predators about the possession of secondary defenses (chemical, physical, or behavioral), which render the prey unprofitable (Poulton 1890). Predators have an unpleasant experience upon attack, which they will associate with the prey's appearance in future encounters. Thus, predators will learn that this particular type of prey should be avoided. While color polymorphism is favored in cryptic prey (see above), it is thought to be inconvenient for aposematic species. This is because variation in warning signals might make it more difficult for predators to learn their association with prey unprofitability.

Aposematic species may resemble each other, making it easier for predators to learn to avoid them. This is known as *Müllerian mimicry* and leads to so-called "mimicry rings," where multiple defended species in the same area possess similar colors and markings. One example is the prevalence of yellow and black stripes across many wasp and bee species. Such mimicry can also be exploited by prey species without secondary defenses. These undefended species can mimic the appearance of defended ones and take advantage of predators having learned to avoid them. This is known as *Batesian mimicry*. For example, humans, along with many other predators, now associate black and yellow stripes with the stings of wasps and bees, but many harmless hoverfly species also have black and yellow stripes. The hoverflies then benefit, as fewer predators are likely to risk attacking them, for fear of being stung. Likewise, some harmless colubrid snakes mimic the color patterns of the deadly

coral snakes (Fig. 1g) obtaining protection from predators.

Animals can also deter predators through threat, or warning, displays. These can include both honest displays, such as those of tarantulas that draw attention to the animal's defenses (in this example fangs), and dishonest, or bluffing, displays, where an animal attempts to appear more dangerous than it truly is. Many mammal species, for example, erect their fur when threatened in order to appear larger. A similar tactic is used by some frogs, which inflate their bodies with air (Fig. 1h).

Aposematic animals can also make use of behavioral displays to advertise their defenses to would-be predators, and just as the physical marking of these species may be mimicked by other for protection, so too are these behavioral responses. Nonvenomous snakes in the family Colubridae will often perform similar body flattening or inflating displays as venomous ones when threatened. This similarity can be further enhanced by so-called head-triangulation, whereby snakes flatten their head in order to make it appear more triangular, like those of vipers (Valkonen et al. 2011).

Finally, animals may try and convince a predator that they will not make a suitable meal by pretending to be dead. Also known as thanatosis, this strategy relies on the fact that many predators only capture live prey and is found in a wide variety of taxa ranging from insects to frogs and mammals. Indeed, an alternative name for this behavior is "playing possum" after the common opossum (*Didelphis marsupialis*), which has been recorded to feign death for up to an hour following attacks by dogs (Francq 1969).

## Preventing Subjugation: *Fight or Flight*

Before they can be eaten by predators, prey must be subjugated. Perhaps the best-known mechanisms for preventing this are fighting or fleeing. While many animals fight back by whatever means are available to them, for example, by biting or scratching, others have weapons, such

as the antlers of deer or the claws of crabs, that can be used against would-be predators. Notably, most animal weapons are not solely for defense against predators, but often play an important role in feeding or sexual competition. Deer, for example, use their antlers (Fig. 1i) during male-male competition, while male fiddler crabs use their large claws to court females (Pope 2000). Thus the antipredator function of weapons may often be secondary. In contrast, other mechanisms for avoiding subjugation are highly specialized. Physical defenses such as spines can make it difficult for predators to approach or attack. Some of the best-known physical defenses are the quills of porcupines and the spines of hedgehogs. As well as physical, defenses can also be chemical. Bombardier beetles can spray would-be attackers with a mix of toxic chemicals. These beetles store hydroquinone and hydrogen peroxide in specialized glands. When threatened, the compounds are secreted into a chamber near the tip of the abdomen and their oxidation and decomposition creates a powerful chemical reaction which produces a hot jet of fluid. Ejecting noxious chemicals at predators is not only confined to beetles, indeed the most famous animal to use this kind of defense is a mammal, the skunk, which sprays its enemies with foul-smelling volatiles such as sulfides.

Another strategy to escape capture is to startle or scare the attacker. This can be done in a number of ways, from appearing to suddenly change size, to flashing bright colors or making a loud noise. These kinds of defenses differ from aposematism in that they do not rely on predator learning, but instead aim to elicit the predators fear or startle responses, or simply overwhelm their senses momentarily, giving the prey a chance to escape. One example is the mountain katydid (*Acripeza reticulata*), which is a type of bush cricket found in Australia. Mountain katydids appear dull brown until startled, when they lift their wings to flash their brightly colored abdomens (Umbers et al. 2017). Another example is the eyespots displayed by some butterflies (Fig. 1j). These are markings with circular shape that are thought to look like vertebrate eyes and are thus believed to

intimidate or startle predators making them hesitate to attack.

Finally, many, if not all, strategies to avoid subjugation rely on fleeing. Once the predator is startled, injured, or simply distracted, prey must escape to safety. Escape may entail more than simply running away, however. Many lizard species possess tails that detach when pulled, other animals such as crayfish can detach legs, and this ability is widespread across arthropods. This is done through processes known as *autospasy* (when the body part is lost in response to an outside pressure, such as pulling) or *autotomy* (when the part can be detached by the animal itself), which allows animals to sacrifice body parts with minimal blood loss. This enables them to escape, leaving their attacker with only a leg or tail. Fish scale geckos can even shed their skin when grabbed (Scherz et al. 2017). Some lizards take this one step further and have bright markings on their tails to encourage would-be predators to strike there (Castilla et al. 1999). This sort of misdirection is also seen in insects, like the butterfly *Bicyclus anynana* which has conspicuous *eyespot*s along the margins of its wings. These have been shown to draw the attention of attacking preying mantids, which are more likely to strike at the wings, rather than the head or body, of butterflies with these eyespots (Prudic et al. 2014).

Another strategy to avoid attack and subjugation is *motion dazzle*, whereby patterns with high contrast (i.e., stripes, bars, or zigzags) make it difficult for a predator to assess accurately the speed or direction of a moving prey (Thayer 1909). This is because such patterns may create a visual illusion of reduced speed or immobility. Previous correlational work with snakes (Jackson et al. 1976), poison frogs (Rojas et al. 2014), and lizards (Halperin et al. 2016) has suggested the matching between color patterns and movement, such that animals with striped or elongated patterns move linearly and/or at higher speeds, two movement characteristics that may accentuate the visual illusion.

However, animals are often most vulnerable to predators when they are unable to escape, for

example, as eggs or during larval or early development stages. For this reason many species actively protect their young through mobbing or otherwise distracting predators that get too close to their offspring. Other species, such as the red-eyed tree frog (*Agalychnis callidryas*), have embryos that are capable of hatching prematurely when the egg masses are attacked by snakes (Warkentin 1995).

### Preventing Consumption: *The Last Line*

Even once caught and subdued, animals have one last hope of escape if they can prevent their captor from actually consuming them. This can be achieved in one of several ways, by being toxic or poisonous, by tasting bad, or by simply being too difficult to swallow. Many animals use chemicals to render themselves toxic or unpalatable. These can be sequestered from their diet or created by the animals themselves. As they are unable to move away from predators, plants often use chemical defenses (also known as secondary metabolites or allochemicals) to deter herbivores. However, some herbivores have not only evolved strategies to deal with these chemicals, but can also store them in their own bodies for defense. This strategy is particularly widespread in insects and examples include monarch butterflies (*Danaus plexippus*), whose larvae sequester cardenolides from milkweed plants (Brower and Fink 1985), pine sawflies (*Neodiprion sertifer*, *Diprion pini*), who sequester resin acid from pine trees, and bella or rattle box moths (*Utetheisa ornatrix*), which sequester pyrrolizidine alkaloids from the seeds of their host plants (Conner 2009). Burnet moths (family Zygaenidae) (Fig. 1e), on the other hand, are also capable of sequestering cyanide compounds from their food plants and use them as a defense against predators across their different life stages. However, when this source is scarce, they are able to synthesize these compounds *de novo* (Zagrobelyny et al. 2007). Many of these insect species are also aposematic, but predators may “taste-reject” them even if they are not deterred by their warning

signals. But there are examples of toxicity among vertebrates too. Poison frogs, for instance, can sequester toxins from their diet, which consists mostly of ants and mites. These secretions (Fig. 1k) contain mostly alkaloids, several of which are neurotoxins (Saporito et al. 2012); one of them, batrachotoxin, which is also a cardiotoxin, is one of the most potent alkaloids known and the reason why the golden poison frog was given the name *Phyllobates terribilis*. Some species of harlequin toads, California newts (*Taricha torosa*), and puffer fish (family Tetraodontidae) are known to possess another potent neurotoxin called tetrodotoxin (see below). In most cases, its origin is uncertain but, at least in the case of the puffer fish, it has been shown to be produced by symbiotic bacteria (Magarlamov et al. 2017).

### “Social” Defenses: *Safety in Numbers*

Many of the defenses described above work more effectively in groups. For example, aposematism has been shown to be more beneficial when animals aggregate (Riipi et al. 2001). However, there are also strategies that rely on social behavior. The first of these is group *vigilance* behavior, which is widely used in several bird and mammal species. Vigilance simply means that animals are aware of their surroundings in order to detect potential predators; however, remaining vigilant can interfere with other behaviors such as feeding. By foraging for food in groups, animals can reduce their own vigilance while relying on the combined senses of the group in order to remain safe. Some species, such as meerkats (*Suricata suricatta*), take this one step further by having “sentries,” i.e., individuals who keep watch for predators while the rest of the group forages.

In addition, while many species rely simply on sensing their neighbors fleeing to communicate a threat, some also give specific *alarm signals*. Vervet monkeys (*Chlorocebus pygerythrus*) are famous for having three distinctive alarm calls, one for leopards (*Panthera pardus*), one for snakes, and one for eagles. Many small birds,

including tits from the family Paridae (Fig. 11) will produce so-called mobbing calls in response to nearby predators. These calls not only function as alarm signals, communicating the presence of the threat to others, but they also harass the predators and recruit other birds to join the mobbing. Mobbing birds will stay in the area of the predator, performing mobbing calls and displays. These calls can also vary depending on the type of predator and how dangerous it is. Mobbing may also include attacks on the predators, with the aim of preventing them from hunting or driving them out of an area. Notably, these mobbing calls can warn and recruit members of other species, and multi-species mobbing groups are often observed. Despite this, Paridae species vary considerably both in how much information their mobbing calls convey about the threat posed by predators and how this information is encoded in their calls (Carlson et al. 2017).

### **How Do Antipredator Strategies Evolve?: An “Arms Race” Between Predators and Prey**

Predators need to feed, and prey must avoid being eaten. Thus, predators continuously evolve better tactics to ensure they can successfully find, subjugate, and consume prey, while prey improve their defenses to prevent predators from succeeding. This has been likened to an “arms race,” in which an improvement in one side’s abilities results in a corresponding improvement by the opposing side. For example, as predators improve their visual acuity in order to increase prey detection, prey might elaborate their camouflage strategies or adopt different spatial distributions that make it more difficult for predators to find them. Likewise, as prey evolve toxins to avoid being consumed, predators may develop detoxification abilities or toxin resistance mechanisms. Such is the case in garter snakes (*Thamnophis sirtalis*), which have evolved molecular mechanisms to avoid getting intoxicated by the powerful tetrodotoxin from rough-skinned newts. Tetrodotoxin (TTX) is a

neurotoxin that blocks the sodium-potassium channels in nerve cells, leading to paralysis. Garter snakes are capable of avoiding this effect of TTX because they have evolved sodium channels with a different shape, impeding the TTX molecule from binding them. Furthermore, garter snakes from populations co-occurring with the newts have shown to be more resistant to TTX than those from populations without co-occurring newts (Brodie and Brodie 1999).

### **Conclusions**

Predation is undoubtedly one of the greatest forces shaping evolution, and this is reflected in the huge diversity of defense strategies seen in nature. Animals use every possible tool they have available in order to survive. However, no defense is perfect as predators are also constantly adapting to overcome the barriers prey put up against them. As a result many species use multiple defense strategies and may switch between radically different strategies as the predation attempt progresses. Indeed, a single species of frog found in Malaysia has been found to respond to attacks by “fleeing, feigning death, crouching, hiding among leaf litter, diving underwater, inflating the body, body-raising, defensive call(s), and bladder discharge” (Shahrudin 2016). Furthermore, a single strategy can act across more than one stage. A frog that inflates itself may threaten and dissuade predators with its increased size, but if this fails the inflation may also serve to make it too large to swallow. Thus, species can alter their defensive behaviors based on the identity of their attacker, and if one strategy fails to deter them they simply switch to another.

### Introduction

The chance of prey to escape predation strongly depends on its ability to detect the predator before getting attacked. In order to avoid potential lethal attacks, prey species need to be constantly vigilant. At the same time, they need to engage in other activities such as feeding and mating. This creates trade-offs between the time invested in antipredator vigilance and all other activities. Optimizing the outcome of such trade-offs requires a precise knowledge of the predator appearance in order to minimize false alarms and at the same time maximize correct identification. Predator recognition can be either inherited or learned, for instance, based on own or public information. To recognize the presence of a predator, prey animals may employ various cues, often involving different modalities such as olfactory, visual, or acoustic information. Moreover, the chances to detect a predator will further increase when several individuals are vigilant. In this chapter we will first elucidate the different mechanisms enabling animals to differentiate between non-dangerous animals and predators. We will then introduce the different cues animals use to detect the presence and motivational state of predators. Finally, we show how the presence of group members increases a prey's chance to detect predators and how such information about risk is transferred within the group.

### How to Recognize a Predator?

Many animals, including humans, show inborn fear reactions toward other potentially dangerous

animals (Davey 1995). These prey species do not need to learn respective predator cues but intrinsically react with appropriate behaviors after detecting the predator. In contrast, others need to learn about the potential danger of unknown animals, often through repeated experiences with predators, either by direct contact or by observing others (Brown et al. 2011). Additionally, inborn predator recognition might be fine-tuned by further learning particular predator phenotypes. Whether innate recognition or learning is involved in predator detection often depends on the ecology of the respective species (Brown et al. 2011). Learning to detect predators is more beneficial when the risk of encountering a given predator is variable on a spatial and temporal scale (Brown et al. 2011). On the contrary, genetically determined predator detection is beneficial in species that face always the same predators (Brown et al. 2011). Interestingly, many prey animals are able to generalize learned predator recognition to other predatory species, which are similar in appearance and smell. This enables prey to reduce the costs of learning to detect new predators because potentially dangerous encounters can be reduced (Brown et al. 2011).

### Genetically Determined Recognition

Many animals own an inherent, genetically fixed concept of the phenotypic appearance of a predator. Such concept can be very coarse, following simple rules of thumb (e.g., *avoid all animals that are bigger than you are*). However, such coarse recognition templates will readily lead to false alarms, which might prevent individuals from foraging or mating and which will lead to constantly having acute stress responses. It is thus not surprising that in many cases, more fine-tuned inherent recognition templates have evolved. The cichlid fish *Neolamprologus pulcher*, for example, is able to spontaneously differentiate between predatory and herbivorous cichlids that are of similar size (Fischer et al. 2014). It, thus, does not follow the rule “*all large fish are dangerous*” but rather uses more subtle differences in the respective fish's appearance. Importantly, these behaviors were observed in laboratory-reared fish that had never experienced heterospecifics

before, indicating that the fine-tuned recognition template is inherent and not learned (Fischer et al. 2014).

### Nongenetically Determined Recognition

Information about the predatory environment can also be nongenetically transmitted between generations from parents to offspring. Mothers are the key interface between the current environment and future generations. So-called non-genetic maternal effects are common in many species and lead to responses in offspring, which might not necessarily be adaptive. When offspring responses are adaptive, mothers use cues from the current environment to prepare their offspring for the potential future environment. For example, in yellow-legged gulls (*Larus michahellis*), offspring from mothers that were exposed to predators show an increased antipredator response compared to offspring from mothers that were not exposed to predators (Morales et al. 2018). Adaptive responses are particularly beneficial when environmental conditions of mothers match the environmental conditions experienced by their offspring. However, maternal exposure to predators can also have detrimental effects on offspring behaviors and survival. For example, in three-spined stickleback (*Gasterosteus aculeatus*), offspring from mothers exposed to predators show less efficient antipredator behaviors compared to offspring from mothers that did not experience predators (McGhee et al. 2012). In such cases mothers may experience acute stress while exposed to predators and consequently lay eggs of lower quality, resulting in less developed and less adapted offspring.

### Learned Recognition

Some prey species either don't possess a genetically determined template to recognize predators or do not show appropriate responses. In the first case, animals need to learn to detect predators in order to assess potential danger. For these animals it is crucial to gather information about the identity of potential predators either through personal or social experiences. Gathering personal information can be very costly as animals that misjudge the prevailing danger have the

considerable risk of getting injured or killed while learning. Here, employing the knowledge of other, more experienced individuals can be beneficial. Social information about predators are transmitted from one individual to another, for example, through alarm calls, chemical warning substances, or sentinel behavior. Observing experienced individuals interacting with predators is also an effective way to gain information about successfully interacting or evading predators. For example, juvenile Siberian jays (*Perisoreus infaustus*) start mobbing predators only after observing a knowledgeable individual mobbing the same predator species. This information is crucial for juveniles as it improves the survival during the first winter, when they interact the first time with predators (Griesser and Suzuki 2017).

## Sensory Ecology of Predator Detection

Prey animals use a broad range of different cues to detect predators. The used sensory modality strongly depends on the species ecology. For example, visual cues play an important role in terrestrial, diurnal animals. However, when vision is hampered, for example, in nocturnal or aquatic species, other modalities become more important. Finally, cues from different modalities are usually not used in isolation. Instead, prey animals gather multimodal information to optimize their chances to detect a predator as early as possible. In the following we introduce how animals use different modalities to detect predators.

### Visual Detection

Vision is an accurate and reliable sensory modality to detect predators. Visual cues are transmitted fast and can be perceived over long distances. Accordingly, many diurnal animals rely on visual cues when prospecting potential danger. Here, a large field of view without head movements is beneficial. Therefore, the eyes of most mammal prey species, like antelopes, mice, and rabbits, are located far apart from each other on opposite sides of the head. This increases the field of view and allows them to scan a huge space range on both sides of their body. Similar adaptations occur in

many fishes or birds. Woodcocks (*Scolopax rusticola*), for example, have a nearly panoramic view of 359° in the horizontal plane (Cronin 2005). However, this increase comes at the cost of reduced perception of depth and a hampered ability to see in 3D.

As an adaptation to the good eyesight of many prey species, some predators have evolved cryptic coloration, making it difficult for prey to spot them. Many sharks, for example, show different color patterns on their dorsal and ventral body side. While the dorsal part is dark, the ventral part is often lighter. Seen from above, the dark color camouflages the shark against the dark deeper water below, while from below the pale color conceals the shark against the lighter water surface (*Countershading*, Marshall and Johnsen 2011).

Despite the benefits of vision to transfer information fast and over a long distance, vision is not always the best modality for predator detection, as the transmission of visual cues is easily hampered. For example, visual cues are blocked in highly structured habitats like forests. Furthermore, visual perception is limited during the night. Finally, vision is strongly reduced in aquatic systems due to high turbidity or the lack of light in deeper water bodies. Under such conditions other modalities gain importance.

### Chemical Detection

Prey animals use a variety of chemical cues to detect predators. Such chemical cues can be produced by predators, conspecifics, or other prey animals (Hettyey et al. 2015). Predator-derived cues are mostly released unintentionally. As they reveal the predator's presence to the prey, they are indeed disadvantageous for the producer, though they might have functions, for example, in intra-specific communication. Furthermore, smell might arise from the integument of the predator or from its digestive tract. Finally, feces or urine might contain parts of the predators' gut flora, as well as metabolites of digested prey items (Hettyey et al. 2015). Prey animals readily use such olfactory information to detect the presence of a predator and adjust their behavior accordingly. For example, small freshwater crustaceans

(*Gammarus pulex*) avoid the smell of predatory fishes and form social aggregation, even if the predators were not fed on gammarids before (Baldauf et al. 2007; Kullmann et al. 2008). Similarly, many snake species show characteristic defensive behaviors to the odors of snake-eating snakes, and rats respond with characteristic defense and fear responses toward cat odors (Dielenberg and McGregor 2001). Other predator defense responses might be long-lasting or even irreversible, such as morphological adaptations. For example, many tadpoles develop stronger tails in the presence of a predator's olfactory cues, allowing them to escape faster (Hettyey et al. 2015).

Chemical information about the risk of predation can also be prey-borne and produced when animals are stressed, attacked, captured, or digested (Hettyey et al. 2015). Such chemical cues might be passively released from injured prey tissue and serve others as information. This phenomenon has been already described by Karl von Frisch (1942), one of the founders of modern ethology. He found that European minnows (*Phoxinus phoxinus*) show an intense fear response when exposed to conspecific skin extract imitating a predation event and coined the term *Schreckstoff* for such damage-release cues. While some of these damage-released cues are passive by-products of the predatory act itself, others have evolved to act as active signals for warning other individuals. These signals are costly to produce, and do not directly benefit the sender, which is why they are a puzzle in the evolution of the communication of risk. One solution is that damage-release signals might have evolved mainly in species that live together with close kin. Warning relatives may hence lead to indirect fitness benefits for the sender. For example, sea anemones (*Anthopleura elegantissima*) live in colonies of genetically identical individuals. Injured individuals release a pheromone that induces a typical self-defense response in neighboring individuals, which retract and protect their tentacles (Howe and Sheik 1975). Similarly, honeybee workers (*Apis mellifera*) attack predators threatening their colony by stinging. Stinging is a suicidal act because the sting together with the

whole abdomen stays attached to the intruder. At the same time, the sting continues to simultaneously release venom inside the victim and a pheromone to the outside to attract more worker bees (Breed et al. 2004).

### Acoustic Detection

Acoustic cues are important means to detect predators, especially in habitats with low visibility (Hettena et al. 2014). To discover a predator by acoustic cues, many animals have evolved distinguished hearing abilities to accurately locate sounds. Many herbivore mammals like antelopes, deer, horses, and rabbits are able to move their ears in almost 180°, increasing their acoustic perception and allowing them to accurately locate the origin of sound. Detecting acoustic predatory cues becomes especially important, when predators themselves employ sound waves to find their prey. This is the case in many bats that use echolocation to spot and catch prey insects. These nocturnal hunters emit high-frequency calls and listen to the echoes to determine the size and location of their target (Jones et al. 2016). As a counter adaption, however, many moths and other nocturnal insects can detect the echolocation calls of bats, allowing them to initiate evasive flight maneuvers. A peculiar defense behavior is shown by dogbane tiger moths, *Cycnia tenera*, which produce high-frequency clicks that disturb the echolocation function of the approaching bat (Jones et al. 2016). Finally, acoustic cues also serve as signals that transfer information about an approaching predator from one prey individual to another. Prominent examples are warning calls in many bird species but also in alpine marmots or cooperatively breeding meerkats (Caro 2005).

### Mechanical Detection

Some animals are able to detect approaching predators using mechanical cues. For example, tree-living insects use leaf vibrations to detect the presence of predators (Yack 2016). Thereby, many insects make use of specialized cells arranged in body parts close to the substrate such as legs or antenna (Yack 2016). Furthermore, vibrational signals actively emitted by prey after

detecting a predator also act as an antipredator response to deter the attacker and warn conspecifics.

Fishes, as well as some amphibians and cephalopods, possess a special organ that consists of neuromasts located around the head and along the lateral part of the body. In fishes, these neuromasts are arranged in a long line along the flank, which gives the organ the name *lateral line* (Janssen 2004). The neuromasts are sensitive to pressure changes and hence enable the animal to detect fluctuations in water pressure caused by the movement of con- or heterospecifics. As such, they enable the animal to detect the swimming activity of predators. The lateral line system further plays a crucial role in orientation and shoaling behavior, which is the most common antipredator behavior in fishes and tadpoles (Janssen 2004).

### Multimodal Predator Detection

Each of the previously described sensory systems has its own set of benefits and limitations. For example, chemical cues are particularly useful for gaining information about a predator's presence but are not as reliable for gaining information about the exact location of the predator. Here, visual cues can be more reliable. Still, visual cues have their limits when predators are camouflaged or when light conditions are bad. Acoustic cues might easily be overheard because of other background noises. Thus, in order to gain optimal information about the potential presence of a predator, animals commonly use multiple sensory modalities at the same time (Munoz and Blumstein 2012). For example, mosquitofish (*Gambusia affinis*) uses visual and chemical cues to avoid predators, while each cue in isolation would be sufficient to induce the correct antipredator response. Nevertheless, if both types of cues are available at the same time, these fish show an increased antipredator response where individuals almost double their distance from the predator (Smith and Belk 2001). Cues perceived in different sensory modalities can further transfer different information (Partan and Marler 2005). For example, animals might detect the general presence of a predator by recognizing its smell.

Still, they would lack information about the acute risk, which might be provided by additional visual information about the approaching speed. Thus in this case, olfactory information might lead to an increased level of vigilance, while the visual cue will induce a fast flight response.

The use of multimodal cues in predator detection is not only important to increase detection accuracy but also allows to detect predators under fluctuating environmental conditions. For example, changing weather conditions limits the relative importance of single cues (Caro 2005; Saunders et al. 2013). The need to base decisions on multiple cues is not restricted to terrestrial environments but also of importance to aquatic animals. For example, seasonal rainfall will lead to a temporal reduction in visibility in the African Rift Valley Lake Tanganyika, caused by algae blooms and floating sediment. In this environment, the highly social cichlid fish *N. pulcher* uses olfactory and visual cues to detect predators, and both cues lead to comparable antipredator responses (Fischer et al. 2017).

In recent years, most natural habitats faced drastic human-induced changes, including altered visibility due to algal blooms caused by eutrophication and soil import, increased noise levels, changes in water chemistry, and chemical pollution (Hildebrand 2009; Barber et al. 2010). These changes have strong impacts on predator detection abilities in many species. For example, traffic noise impacts the production and perception of alarm calls in great tits (Templeton et al. 2016) and impacts the use of alarm calls in dwarf mongooses (Morris-Drake et al. 2017). Using different modalities might allow animals to increase their success in predator detection in such modified environments. Still, the relative importance of different sensory modalities governing predator-prey interactions in changing environments is mostly unknown (Hale et al. 2017). Human-induced perturbations might not only influence predator detection in one modality but might influence other sensory systems as well. For example, traffic noise on land and underwater hampers the recognition of chemical cues associated with predation risk in fish and mammals (Morris-Drake et al. 2016; Ferrari et al. 2018).

## Predator Detection as a Driving Force in Social Evolution

Perfect protection from predators requires constant vigilance. However, animals also need to invest time in feeding or mating, and these activities are reduced while being vigilant. Solving the problem of allocating time between being vigilant and other activities is challenging, and diverse strategies exist, which are dependent on the social organization. Most solitary animals increase vigilance only during dangerous situations and decrease vigilance in safe situations. This requires individuals to constantly assess the local predation risk, which has been termed the threat-sensitive assessment of risk (Brown et al. 2011; Fischer et al. 2017) and is an important way to reduce costs of antipredator behaviors. However, this requires animals to possess a reliable estimate of the local predation risk, which might not always be possible. Other animals live in groups, where vigilance can, for instance, be split among group members.

### Predator Detection and Sociality

The risk of predation is probably the strongest force leading to group living in animals. One benefit of living in groups is that the chances of at least one individual detecting the predator and alarm the rest of the group increases with increasing group size (Pulliam 1973). This *many eyes effect* exists in many animal species (Davies et al. 2012). Such detection benefits do not necessarily require more eyes as it is nicely illustrated by a colonial social spider (*Metepheira incrassata*). Here individuals join together and build large communal webs. Individuals within these colonies gain antipredator benefits by detecting mechanical vibrations transmitted through the communal web when other colony members are under risk (Uetz et al. 2002).

An individual in a group might not only benefit from an earlier predator detection but might further share the costs of being vigilant by alternating scanning behaviors between group members. As a consequence, the vigilance of the whole group will be increased, while each individual has to be less vigilant compared to solitary conspecifics

(Beauchamp 2015). Such beneficial effects of group vigilance can be further enhanced, if group members actively warn others, for instance, by alarm calls. The information content of such alarm calls can be highly fine-tuned. For example, meerkats (*Suricata suricatta*) emit different alarm calls depending on whether the predator is a bird of prey or a snake (Manser 2001). Furthermore, the calls might indicate different grades of urgency. This enables other group members to show the respective adequate antipredator behaviors.

While alarm calls are beneficial for recipients, producing such calls is costly in terms of time and energy spent. Furthermore, the caller might increase its risk of being spotted and attacked. Still, emitting alarm calls might lead to direct and indirect benefits for the producer as well as for the receivers within the group, which is why alarm calls are widespread (Caro 2005). For example, alarm calls in the common redshank (*Tringa totanus*) cause the entire flock to fly off together, which might confuse the predator (Will Cresswell 1994), and directly increase the survival chances of the caller. Furthermore, the caller will gain indirect fitness benefits when warning relatives, which therefore are more likely to produce offspring sharing genes with the caller. Belding's ground squirrels (*Urocitellus beldingi*), for example, emit alarm calls more readily when accompanied by relatives (Jill 2010). The most pronounced forms of shared vigilance can be found in highly social species, such as cooperatively breeding meerkats. Here, the sharing of vigilance between group members has evolved into a sentinel system where some individuals entirely stop foraging for a specific period and watch out for predators to alarm the rest of the group. Here, the individual nutritional state is a major predictor of sentinel activity with hungry individuals resuming to forage and saturated individuals acting as sentinels (Clutton-Brock et al. 1999).

Finally, alarm calls are not restricted to within-species communication. Indeed, many birds and mammals react to alarm calls of other species, especially when both species share the same predators (Meise et al. 2018). For example, dwarf

mongooses (*Helogale parvula*) respond to alarm calls of tree squirrels, with which they share predators, but not to alarm calls of baboons, which are vulnerable to different predators (Morris-Drake et al. 2017).

### Reliability and Cheating

In contrast to using own information, obtaining information about predation risk from others poses the risk of being unreliable and inaccurate. This is, for example, the case when predators differ in threat depending on species, size, sex, or age of the prey individual. Consequently, animals that have the choice between different sources of information shall incorporate the reliability of the respective sources in their anti-predator response. For example, zenaida doves (*Zenaida aurita*) show a higher level of vigilance during playback experiments using calls from red-tailed hawk (*Buteo jamaicensis*) compared to playbacks of conspecifics' wing whistles, which serve as alarm cue (Barrera et al. 2011). The reliability of social information is also dependent on the identity of the sender. For example, dwarf mongooses reduce their vigilance more strongly following warnings of experienced dominant individuals compared to subordinate and more inexperienced individuals (Kern et al. 2016).

A further source of unreliability is the probability of deceptive attempts by the caller. Fork-tailed drongos (*Dicrurus adsimilis*), for example, mimic alarm calls of other species when they handle food. Target species like meerkats and pied babblers (*Turdoides bicolor*) readily react with a fleeing response, abandoning their food, which is then taken by the drongo (Flower 2011).

### Conclusion

To survive in risky environments, prey animals need to detect predators before being attacked. Some prey species have a genetic predisposition to detect and recognize predators, whereas others need to learn appropriate responses by direct or indirect experiences. Visual, olfactory, chemical, acoustic, and mechanical cues are used in isolation or in combination to detect predators and to

communicate predation risk to others. Finally, the benefits of increased predator detection and defense are probably one of the main driving forces in the evolution of animal sociality.

Prehensile Tail

Andrew Deane  
Department of Aantomy and Cell Biology,  
Indiana University School of Medicine,  
Indianapolis, IN, USA

*Prehensile tail:* The tail of any vertebrate that is adapted for grasping can hold objects or can support some or all of the body weight of animal while stationary (i.e., feeding posture) or during locomotion.

*Anthropoid:* A primate belonging to the suborder Anthropeidea that has a fused mandibular symphysis, fused frontal bone, postorbital closure, a greater reliance on vision than olfaction, and lacking a rhinarium, tapetum lucidum, grooming claws, or dental comb; the group of primates including old and new world monkeys, apes, and humans.

*Platyrrhini:* A radiation of neotropical anthropoids belonging to the infraorder Platyrrhini and defined by their biogeographical distribution (i.e., Central and South America), nasal, auditory and cranial morphology, and dental formula (2133/2133).

Prehensile tails are known for four of the seven classes of vertebrates (Table 1). They are differentiated from nonprehensile tails by being adapted for grasping, holding objects or supporting some or all of the body weight of animal while stationary (i.e., feeding posture) or during locomotion. “Prehensile” is derived from the latin *prehendere* (to take hold of, to grasp). This adaptation has arisen many times and independently in fish, amphibians, reptiles, and mammals. In mammals, this adaptation has evolved independently at least 14 times among 50 genera (representing 14 families) including separate origins in the anthropoid New World primate (Platyrrhini) family Atelidae (woolly, spider, woolly spider, and howler monkeys) and in some members of the family Cebidae (capuchin monkeys) (Emmons and Gentry 1983; Organ et al. 2009; Organ 2010) (Fig. 1). The separate origins of these similar and metabolically

**Prehensile Tail, Table 1** List of prehensile- and semi-prehensile-tailed mammals, reptiles, amphibians and fish

(Emmons and Gentry 1983; Organ 2010)

expensive anatomical structures in diverse lineages of arboreal mammals suggest that prehensile tails are an effective adaptation for negotiating arboreal environments (Emmons and Gentry 1983; Organ et al. 2009; Organ 2010).

Prehensile tails among platyrrhine anthropoids may have arisen as an adaptive accommodation

**Prehensile Tail, Fig. 1** \*Indicates a platyrrhine genus with a prehensile tail. Although species of the genus *Saimiri* are members of the family “Cebidae” they do not retain a functioning prehensile tail into adulthood and are effectively nonprehensile-tailed (Reproduced from Organ (2010))

for larger body sizes in dense tropical canopies (Napier and Napier 1967; Grand 1972, 1977), a postural adaptation for feeding that frees up the forelimbs (Rosenberger 1992; Bergeson 1996, 1998) or else a response to mechanically compliant forest canopy substrates (Emmons and Gentry 1983; Organ 2010). Emmons and Gentry (1983) have suggested that canopy distribution and composition play an important role in the selection for and distribution of mammals with prehensile tails. There are fewer gliding or prehensile-tailed mammals in Africa where the canopy is dense and there is an abundance of lianas yet in Southeast Asia, where the canopy is less dense and there is a scarcity of lianas, there is a relative increase in the number of gliding species. Likewise, in the neotropics of South and Central America, where there is an increased number of palms, more fragile arboreal supports, and an intermediate abundance of lianas, prehensile-tailed mammals are most abundant. However, Australia and New-Guinea are home to a number of mammal

species that are both gliders and that have prehensile tails.

Tails are comprised of caudal vertebrae. Tail length is a direct function of the number of caudal vertebrae. Caudal vertebrae can be identified as either “proximal” or “distal” depending on their specific morphology. Proximal caudal vertebrae are typically shorter craniocaudally and have well-developed neural arches with a single set of transverse processes. Proximal caudal vertebrae articulate via intervertebral disc joints as well as zygapophyseal joints associated with the neural arch. Hemal processes are found on the proximal and ventral surfaces of proximal caudal vertebrae and serve as attachment points for the hemal arches (“chevron bones”) that function as muscle attachment sites. Distal caudal vertebrae are longer craniocaudally and lack a neural arch. They have two sets of transverse processes (one proximal and one distal) and articulate via intervertebral disc joints only. The last vertebra of the proximal caudal region is the “transition vertebra” and is identified by the presence of zygapophyseal joints only at its proximal end. Craniocaudal vertebral length increases throughout the tail from proximal to caudal until the “longest caudal vertebra” (which is always distal to the “transition vertebra”) and then steadily declines to the terminus of the caudal sequence (Organ et al. 2009; Organ 2010, 2016).

Prehensile-tailed platyrrhines differ morphologically from nonprehensile-tailed platyrrhines. Prehensile-tailed taxa have longer proximal regions comprised of a greater number of vertebrae, craniocaudally shorter and transversely wider distal region vertebrae, more expanded transverse and hemal processes (sites of muscle attachment) (Ankel 1962; German 1982; Organ et al. 2009; Organ 2010), and craniocaudally expanded sacroiliac joints (Ankel 1962). The dorsal and ventral caudal musculature in prehensile-tailed platyrrhines crosses fewer joints to permit finer neuromuscular control of individual joints (Lemelin 1995), and the lateral flexor musculature is more developed to generate significantly higher maximum tetanic tension (Organ et al. 2009). Caudal vertebral cross-sectional geometry in prehensile tailed platyrrhines is consistent with

greater resistance to bending and torsion (Organ 2010). Prehensile tailed platyrrhines have larger and more convex intervertebral articular surfaces to permit a greater range of motion (Deane et al. 2014). Morphological differences between prehensile-tailed and nonprehensile-tailed platyrrhine muscle attachments, PCSA, caudal vertebral robusticity, and resistance to bending and torsion are accentuated in the distal caudal region (Organ et al. 2009; Organ 2010). It is presumed that proximal caudal vertebrae of prehensile-tailed and nonprehensile-tailed platyrrhines are less divergent morphologically given the similar functional demands in this region of the tail (i.e., both groups abduct, adduct, flex and extend their tails; German 1982). Regardless, cross-sectional geometry conferring enhanced bending resistance and increased intervertebral articular surface area and surface convexity differentiate the proximal caudal vertebrae of prehensile-tailed and nonprehensile tailed platyrrhines.

The functional capabilities of mammals with prehensile tails are not uniform. Emmons and Gentry (1983, p. 513) define a prehensile tail as “one which can support alone the weight of the suspended body” and a semiprehensile tail as one that “can be wrapped around branches and support a significant part, but not all, of the body weight.” Although there is not universal consensus on the adoption of this terminology (i.e., prehensile vs. semiprehensile), prehensile-tailed platyrrhines do differ in their frequency and mode of tail-use. Cebines use their prehensile tails to brace themselves against a substrate in a tripod posture during feeding and resting, but infrequently use their tails to suspend their entire body weight (Bergeson 1996; Bezanson 2012). Like cebines, atelines use their tails in postural and feeding behaviors, but also use their tails in hindlimb-assisted tail suspension and during tail-only suspensory locomotor behaviors (Bergeson 1996; Bezanson 2012). Despite these behavioral differences, ateline and cebine tails differ morphologically only by the presence of a hairless ventral friction or “volar” pad (Organ 2016) and more well-developed dorsal caudal musculature (Lemelin 1995; Organ et al. 2009) in the former. In contrast, the cebine prehensile tail is

completely covered with hair (Organ 2016) and the dorsal caudal musculature is developed as in nonprehensile-tailed platyrrhines (Lemelin 1995). Likewise, atelines have four distinctive epicritic histologic mechanoreceptors in the skin covering their volar pad (Meissner’s, Pacinian, and Ruffini corpuscles, and Merkel discs). However, the ventrodiscal tail skin of cebines only contains two of these (Ruffini corpuscles and Merkel cells) suggesting that group lacks some of the tactile capabilities of atelines (Organ et al. 2011). Nonetheless, features such as the well-developed ventral caudal musculature, the strong estimated structural mechanical properties of the caudal vertebrae, and the relatively longer proximal tail region in cebines are convergent with those properties of the ateline prehensile tail (Organ et al. 2009; Organ 2010) and cebine prehensile tails appear as a morphological intermediate between the tails of atelines and the tails of nonprehensile-tailed platyrrhines.

## Definition

Play involves exaggerated, “nonserious” versions of functional species-typical behaviors and appears to be more about the behavior itself than the usual function of that behavior when seriously deployed (Pellegrini et al. 2007). Fantasy, or *pretend play*, has the added characteristic that the player/players are knowingly and intentionally applying a mental representation of a real-world object, person, or action to a substitute object, person, or action in service of the play (e.g., Lillard 1993).

## Recognizing Play

In a broad sense of the term, play is observed in humans and across a wide variety of nonhuman animal species. It is observed primarily in mammal and bird species, during immaturity, and in safe or familiar environments (e.g., Burghardt

2005; Fagen 1981). Play is a notoriously difficult behavior to define, and exceptions exist for most attempts. Typically, play involves exaggerated, “nonserious” versions of functional species-typical behaviors, with the play appearing to be more about the behavior itself than the usual function of that behavior when seriously deployed (Burghardt 2005; Pellegrini and Smith 2002; Spinka et al. 2001). More specifically, Burghardt (2005) has suggested that, in order to be considered play, a behavior must simultaneously meet five different criteria (p. 70–78):

1. Performance of the behavior is not fully functional in the form or context in which it is expressed; that is, it includes elements, or is directed toward stimuli, that do not contribute to current survival.
2. Behavior is spontaneous, voluntary, intentional, pleasurable, rewarding, reinforcing, or autotelic.
3. Behavior differs from the “serious” performance of ethotypic behavior structurally or temporally in at least one respect: it is incomplete, exaggerated, awkward, or precocious; or it involves behavior with modified form, sequencing, or targeting.
4. Behavior is performed repeatedly in a similar, but not rigidly stereotyped, form during at least a portion of the animals ontogeny.
5. Behavior is initiated when an animal is adequately fed, healthy, and free from stress or intense competing systems.

The ways that play manifest and the extent to which engaging in play impacts the development of individuals seems to vary across species. However, the behavior is widely observed; play behavior has been noted in most mammal species, as well as a number of avian and some reptilian species (Burghardt 1998). The high evolutionary conservation of this behavior and the required resources to engage in it suggest that it is a profitable behavior for juveniles, and, as outlined briefly in Section 1, the consequences of being deprived of the opportunity for play can be devastating. Despite the evidence that play is developmentally important for many species, it has

been challenging for researchers to draw strong conclusions about why it exists.

### Types of Play

The type of play most commonly studied within a comparative framework is rough-and-tumble play, or play fighting. This is a broad term, as the specific behaviors that compose this type of play will differ greatly from species to species. Typically, though, rough-and-tumble play has varying degrees of roughness, is entered into voluntarily, and is associated with positive affect (e.g., Pellis and Pellis 2007). Juvenile rats who have been prevented from engaging in this type of play demonstrate deficits in a range of social activities, from the sexual to the competitive, and produce higher levels of stress hormones than socially reared rats (Pellis and Pellis 2007; Von Frijtag et al. 2002).

Object play has also been observed in non-human species. Dogs and cats frequently engage in object play with their human companions, in games of fetch or attacking a ball on the end of a string. It is likely the case that these behaviors represent predatory behavior being elicited by a nonprey object (Pellis and Pellis 1998). Captive gorillas have been observed engaging in play in which the goal appears to be obtaining an object and keeping it from others, alternately playing the roles of possessor and pursuer (Tanner and Byrne 2010). Outside of primates and predatory mammals, however, object play is fairly limited (Pellis and Pellis 1998).

However, there are many other forms of play. One of the most complex of these may be pretend play, the subject of the current entry. Pretend play is a difficult topic to discuss at length from a comparative perspective, for two main reasons. The first among these is, as noted by Lillard et al. (2011), “... pretend play’s purpose is a mystery. The mystery is this: young children need to adapt to the world as it is, yet in pretend play they contrive the world to be as it is not (p. 286).”

The second difficulty of examining pretend play through a comparative lens comes from the nature of pretend play itself. For the purposes of this work, pretend play is a type of play that falls

under the definition of play provided in the first paragraph, with the added characteristic that the player/players are knowingly and intentionally projecting a mental representation on top of their present situation in service of the play (Lillard 1993; Pellegrini et al. 2007). This is a broad definition, which in itself could cover other sorts of play. For example, rough-and-tumble play could qualify as pretend play if the individuals engaged were assuming the role of specific rivals (e.g., in the case of human children, superheroes). Without the benefit of language, it can be extremely difficult to determine with certainty whether any individual from a non-human species is projecting a mental representation on top of the real world.

### Pretend Play in Humans and Nonhumans

Pretend play has been studied extensively in humans. At 15 months of age, human infants are able to track the pretend actions of others and look longer at events in which a pretender violates their pretend scenario, such as pretending to fill one cup and then “drinking” from a different cup (Onishi et al. 2007). The earliest clear example of the production of pretend play is usually object substitution, in which the player uses one object in their play as a representation of some other object (e.g., a banana being treated as a phone); these behaviors emerge around 18 months of age (Leslie 1987; Piaget 1952). Sociodramatic play typically follows, in which more than one pretender engages in a shared pretend situation. This type of play develops sometime between the ages of 3 and 4 years, and even earlier when the player is scaffolded by an older more skilled partner, such as an older sibling or parent (Lillard et al. 2011; Smith 2016).

Pretend play has long been thought to play a crucial role in early human development, scaffolding development in problem solving, creativity, theory of mind, language, and executive functioning. However, a recent review of the literature has placed doubt on a causal role of pretend play, instead casting pretend play as an epiphenomenon of development within these domains (Lillard et al. 2013). Still others have suggested that pretend play forms the basis for counterfactual reasoning; the ability to engage in

pretend scenarios is what underlies the ability to consider possibilities that have not occurred (Gopnik and Walker 2013; Weisberg and Gopnik 2013).

Given the amount of time spent engaging in pretend play by young humans, we might expect to see this behavior in other social species as well, particularly among the great apes. Interest in pretend play in nonhuman animals, primarily apes, began in with the work of Groos (1898), who characterized play as a pleasing way to engage instinctual behavior before having serious need of those behaviors (see also Mitchell 2002). Potential examples of pretend play have been posited most often for “language trained” apes, but these examples are generally anecdotal and occur very infrequently, especially when compared to human children (Gomez 2008). For example, when Kellogg and Kellogg raised Gua, a chimpanzee, with their son Donald, they observed frequent imitative play from Donald, but almost none from Gua (Kellogg and Kellogg 1933, 1967; Mitchell 2002). The chimpanzee Viki was observed performing toy-pulling actions when not in possession of a toy, even acting as though the imaginary toy were stuck. Yet, after a few weeks the behavior stopped and was not observed again (Hayes 1951; Gomez 2008).

As noted, one of the earliest-to-emerge forms of pretend play in humans is object substitution. That this style of pretend play is early emerging is suggestive that it may be one of the least sophisticated forms of pretending and therefore one of the more likely candidates to be observed in non-human species. However, humans typically have a high interest in objects, manufacture artifacts for a wide variety of purposes, and young humans often have access to a number of objects as toys. The absence of these qualities makes object substitution in nonhuman animals harder to be ascertain: the objects used (rocks, sticks, leaves, etc.) are also the most readily available to them in the wild, negating some of the requirement for substitution. For instance, imagine a young chimpanzee observing her mother using a stone to hammer open nuts on a larger rock. Later, that same juvenile is herself observed banging a small stone against a larger rock, without a nut. Is that young

chimpanzee emulating her mother, is she practicing a not-yet developed skill, or is she pretending to open nuts the way her mother does? In contrast, consider a young girl who has observed her mother using a hammer to mend a fence in their backyard. Later, that child is observed swinging her teddy bear against the wall, shouting “bang! bang! bang!”. The child in that example is engaging in pretend play, but our perception of it as such is guided by the fact that the child is using a toy object and because the child is able to speak and make clear that she is considering nonreal world states.

One potential example of a nonhuman species engaging in pretend play is in that described by Kahlenberg and Wrangham (2010), who spent years observing chimpanzees in Kibale National Park in Uganda. They observed individuals engaging in a stick-carrying behavior, in which a chimpanzee would hold a stick, most often tucked between abdomen and thigh, for extended periods of time as they otherwise engaged in regular activity. The stick carrying fulfilled no obvious immediate purpose and was most commonly engaged in by juvenile females, who appeared to be spreading the behavior among each other (adult females rarely engage in the behavior, and it has not been observed in other groups). Kahlenberg and Wrangham hypothesized that this behavior might be a form of pretend-mothering, noting that the chimps occasionally engaged in mothering behaviors toward the sticks, and on the rare occasions this behavior was observed in adult females, it was in the weeks prior to their first birth, and the behavior ceased following that birth.

The stick-carrying example, however, is complicated by the fact that definitions of pretend play are reliant on the underlying mental state and intention of the player. There is no straightforward way to distinguish whether the stick-carrying apes were pretending to mother the sticks themselves, were pretending to be like other older females, or whether their mothering instincts were being co-opted by a “close enough” visual approximation in the way of a cat chasing a toy mouse.

Likewise, while human children frequently pretend to be favorite characters or role models when engaging in play, can we be certain that

juvenile apes are not pretending to be like their older counterparts when engaging in rough-and-tumble play? Not entirely, though Gomez and Martin-Andrade (2005) point out a number of reasons we should be skeptical of this idea: (1) rough-and-tumble play appears in apes without models; (2) if apes are pretending during play fighting they should pretend to engage in other adult behaviors, but do not appear to; (3) rough-and-tumble play is present in virtually all mammalian species; and (4) even in pretend-capable human children, rough-and-tumble play often occurs without the presence of pretend elements.

## Conclusion

Definitions of pretend play posit that a mental representation of a real-world object, person, or action is applied to a substitute object, person, or action. Human children often make explicit (e.g., verbally) their substitutions, and though the role of pretend play in human social-cognitive development is under debate, there is no question that it is a frequent behavior in children between 18 months and 12 years old. In contrast, there is little evidence to date to suggest that pretend play is common in other animal species.

## Definition

Primary defenses are behavioral mechanisms or morphological adaptations that allow animals to escape detection or attack from predators. Robinson (1969) defined these as defenses that are in

operation before a predator initiates any predatory behavior, whereas Edmunds (1974) focused on the fact that primary defenses operate regardless of whether predators are in the vicinity.

## Introduction

Primary defenses are adaptations to defend against predation that are typically part of the animal's physiology and are thus genetically determined. They are distinguished from secondary defenses, which involve responses made after detection by a predator. Whereas secondary defenses can be innate or learned responses, primary defenses do not require learning or intentional responses on the part of the prey species. They typically constitute a permanent part of the organism's structure or behavioral repertoire. One possible exception is hiding, a behavior that allows an organism to avoid detection. However, it is likely that hiding is largely involuntary and results from the species adapting to live underground, under rocks, or in crevices – sometimes referred to as anachoresis.

Animals can also hide via morphological adaptations such as camouflage, known as crypsis. In this case, the coat and coloration of the animal is such that it blends into its background, making it undetectable by predators. In contrast, disruptive coloration breaks up the outline of the prey's body, as in giraffe and zebras. Some animals like jellyfish are transparent, which makes it difficult to detect them in their aquatic environments. Others like penguins employ countershading, which is dark coloration on one side of their bodies and lighter coloration on the other, so they are difficult to view from the air when swimming, but also difficult to view from below for underwater predators such as sharks. Some of these traits may serve functions other than protection against predation. For instance, penguins' coloration may also assist with UV protection and thermoregulation. Some species even resemble inanimate objects, like walking stick insects. In a special case of Batesian mimicry, the animal's coloration resembles that of an unpalatable species, causing predators to avoid attempting to

consume it. For example, harmless colubrid snakes mimic the pattern of toxic corn snakes even though they are not themselves toxic. In contrast, in Mullerian mimicry, unpalatable species resemble each other to enhance the effectiveness of their coloration. For example, a predator that has been stung by any species of wasp is more likely to be inhibited from attacking a bee's nest as all species exhibit the same distinctive black and yellow stripes.

Other examples of defensive coloration serve as a legitimate warning that the animal is unpalatable or toxic to consume, as in aposematism, which operates in conjunction with physiological traits such as the production of toxins. For example, the brightly colored poison dart frogs are typically avoided by predators that have learned to associate their appearance with violent illness. Aposematic coloration is most likely to evolve in fairly homogeneous habitats (Merilaita & Tullberg, 2005). Not all warning signals are visual, however. For example, the rattlesnake's rattle provides an auditory signal that warns other organisms to stay away. Other species use noxious odors, such as the spray of the skunk.

Other primary defenses built into an animal's morphology include hard armor such as the shell of the tortoise and armadillo, the spines of a porcupine or hedgehog, and explanate margins in insects. Because of the physical investment in developing such defenses, they are likely to evolve in species that are commonly exposed to predation, such as those in open habitats (Shinohara & Takami, 2020). It is important to note that primary defenses are not mutually exclusive with secondary defenses. For many species, both types of trait are employed, but there can be a functional trade-off. Furthermore, a trait like spines that may appear as a primary defense may actually function to prevent the organism from being swallowed once attacked by a predator (Shinohara & Takami, 2020). All of the primary defenses are widespread within insects with spines being typical (Sherratt & Kang, 2018). Defenses are under extreme selection pressure and will diversify in response to variation among predators in different environments (Shinohara & Takami, 2020).

Although it may seem intuitive that primary defenses would be the most adaptive in the sense that prey should avoid predators as early as possible in the predation sequence (Endler, 1991), researchers have found that prey species vary in terms of when they employ defenses (Bateman et al., 2014). Sherratt and Kang (2018) note that when the primary defense provides adequate protection against predation, the organism often fails to evolve any backup behavioral strategies. Primary defenses are more effective in reducing mortality rates, but predators may be able to overcome these defenses (Ruxton et al., 2018). Bateman et al. (2014) modeled the population dynamics of two prey types and a predator specialized to prey upon them. They found that the mechanism of defense would depend upon the prey species' ratio of population growth rate proportional to costs of predation. The results were similar when modeling a generalist predator. Predator-prey relations are among the most informative for demonstrating evolution in progress as predators must continually evolve mechanisms for thwarting prey defenses and prey, in turn, must continually adapt their defenses to survive.

## Primary Somatosensory Cortex

Vishwajit Ravindra Deshmukh<sup>1</sup> and  
Dinesh Kumar<sup>2</sup>

<sup>1</sup>Department of Anatomy, All India Institute of Medical Sciences, Nagpur, Maharashtra, India

<sup>2</sup>JIPMER, Puducherry, India

In the early twentieth century, eminent scientists like Brodmann and Campbell postulated that the well-developed outer surface of the brain can be viewed as identifiable areas performing discrete functions. They had also observed notable histological differences between areas beholding

motor functions and their sensory counterparts. Out of the various granular cortical areas, the region which lies directly behind the central sulcus in the parietal lobe, i.e., the pre-central gyrus, is the primary somatosensory cortex. *Woolsey C.N.* and his colleagues (*Woosley and Van Der Loos 1970*), after their painstaking endeavors related to this area in Macaque monkeys, found that there is a single large representation of the contralateral body surface area in the anterior parietal cortex. The profoundness of the high density points in this strip of area produced localized sensations upon stimulation. Juxtaposing the previous knowledge, it was evinced that this representation was spanning four distinct cytoarchitectonic fields, Brodmann areas 3a, 3b, 1, and 2. Unlike the lesion studies, which can be successfully applied to study the functional localization of certain areas, studies related to somatosensory cortex had predominantly used electrical stimulation evoked potentials.

### **Gross Connectivity of Primary Somatosensory Cortex (S1)**

The principal function of the area is to receive the inputs which originate from the mechanoreceptors. These information conveyed are relayed in two synapses and modulated in the thalamus. By virtue of processing, it guides the detection of mechanical stimuli such as tactile sensation and proprioception. The stimuli are gauged in terms of magnitude and precise location from body surface. Additionally, in humans, the sensations could also be perceived in cognitive dimensions which help in recognizing the shapes and size (*O'Leary et al. 2007*). In clinical settings, testing of these coherent perceptions is used to discriminate the level of lesion.

Based upon the inputs received, S1 can further be subdivided as areas 3a, 3b, 1 and 2. The afferents from the muscles project predominantly to area 3a and to perform the sensorimotor integration, it retains continuity with primary motor area. This sensorimotor projection, which is more pronounced in rodents, acts as a feed-forward circuit when their whiskers get stimulated and helps in

navigation while moving (*Ferezou et al. 2007*). Few studies (*Sherman and Guillery 2013*) have postulated the trans-thalamic pathway via which the projections from the layer V of the somatosensory cortex travel to the primary motor cortex to serve this function. The proprioceptive inputs are processed mainly in area 3a and 2. From the peripheries, cutaneous afferents project to areas 3b (*Sherman 2016*). The inputs from area 3b are usually projected to areas 1 and 2. Area 1 processes the information for texture and area 2 processes regarding size and shape. Thus, it can be ascertained that the loss of function pertaining to this area depends upon the sub-parcellation of sensory functions (*Kaas et al. 1979*). Furthermore, clusters of neurons are compartmentalized in the form of columns, which are the proprioceptive units of the S1. Each column, spanning across the histological layers receive inputs, process them, and send outputs. Inputs, usually from the thalamus are received by layer IV of the cerebral cortex and outputs, going to various regions of the brain emanate from the pyramidal neurons of layer V (*Welker and Woosley 1974*). The neurons occupying particular column is committed to respond when a particular type of receptor in the stipulated body area is stimulated. Similar to visual processing, if one cluster with larger receptor fields responds to all types of stimulation in a particular area, their counterpart clusters tries to process the complex aspects of stimulation.

### **How Submodalities of Touch Are Segregated in the Sensory Cortex?**

*Mountcastle VB* and colleagues (*Mountcastle 1998*) proposed that the cluster of neurons can be segregated further based on their capability to respond to sustained indentations. His experiments, involving penetrations of vertical micro-electrodes in the S1 of monkeys, found out neurons that were responding to the same sort of mechanical stimulus were aligned perpendicularly to the cortical surface and this paved the way for coining the threshold concept related to columnar organizations (*Mountcastle et al. 1990*). When we receive such stimuli, neurons which

respond throughout the stimuli could be deemed as slowly adapting ones and neurons which respond only to the initiation or caseation of the stimuli could be deemed as rapidly adapting. *Romo* and colleagues (*Romo et al. 1998*) found that when animals are presented with pulses resembling vibratory flutter, only rapidly adapting neurons could sense them. There exists controversy regarding what exactly determines the specifications of the cortical neurons with two school of thoughts. One is grounded on the fact that differential inputs to the cortex deciding the specifications and the other pointing the role of functions related to touch such as texture, intensity, and motion of the stimuli.

### Underpinnings Regarding the Sensory Homunculus

The representation of the various areas is usually organized and this can be represented in the form of a disproportionate and discontinuous caricature of the body, the sensory homunculus. The homunculus is oriented in such a way that regions of the head occupy the inferior part; upper limb occupies superior part of the post central gyrus. The sensations from the lower limb and perineum are represented in the medial portions of the gyrus, near the para-central lobule. The reason for disproportionate representation can be rooted back to evolutionary functionality of the particular species. For example, the vibrissae of the rats play the key function in executing the navigation and thus, they are densely represented in the S1. In fact, the sensory signal from each of the vibrissae goes to the committed collection of neurons and they are arranged in the form of barrels. A typical barrel could be described as the oval shaped dense collection of neuronal cell bodies with a hollow in the centre, made of neuropil. The representation of the rat vibrissae or human digits is determined by the combination of genetic factors and inputs relayed by afferents, which determines the specification within the area.

With evolution, the limbs of primates evolved to act as the tactile sensing organs. This change has increased the representation of the hand and

digits to a remarkable extent. In addition, this helps humans in performing precise, fine motor activities in association with cerebellum and basal ganglia. The rich sensitivity of the lips and vague tactile feelings in back of the body can also be explained by this differential representation. Differences in interpretation of the stimulus also depend upon whether it is active touching, otherwise known as haptics, which usually activates multitude classes of mechanoreceptors or passive touching.

### Implications Regarding Somatosensory Cortex in the Clinics

The above discussed knowledge plays an important role in understanding the wide spectrum of clinical presentations in clinical neurology. Sensory discrimination is a complex phenomenon which requires the multitude processing of the entire somatosensory unit. Lesions resulting in compromised functioning of the S1 present with abnormal sensations and feeling of numbness on the contralateral side of the body. The patient could sense the pain and temperature sensations only in a crude form. This is due to the inability to evaluate the precise form, intensity, and location of the presented stimuli. Higher cortical functions such as stereognosis require assimilation of prior inputs, usually the stored associated memories from other parts of the cortex. For example, when two coins of different weight are placed in the hands of blindfolded person, he tries to associate the texture with the memories and identify the object. *Semmes* and colleagues (*Semmes et al. 1960*) proposed that the effect of lesion differs depending upon the side of lesion and this can be attributed to the cerebral dominance. Left-sided lesions tend to impair the sensations of both sides whereas the right-sided lesions have impairments confined to left side alone. On the other hand, right-sided lesions tend to impair the ability to detect the direction of the provided stimuli and tactile maze learning (*Corkin et al. 1965*). Contrastingly, stimulation of S1 often elicits numbness and tingling sensation in the contralateral body surface which are not accompanied by

pain and temperature sensations. This could be evidenced as a part of “sensory march” during the aura phase of seizures related to this area. *Head and Homes* (Head and Holmes 1911) suggested that dysfunction of parietal sensory cortex leads to minor impairments which are mostly missed out during the clinical examination. For example, in such conditions, sensory perception attains fatigue and often, patients find it difficult to distinguish subsequent contacts at same time. Similarly, patients try to disregard the stimuli presented on the impaired side when two stimuli are given simultaneously on both sides (Carmon and Benton 1969). Presumably, this feature could be used to discriminate the type of lesion during routine neurological examinations.

### **Additional Pearls Regarding S1 from the Laboratories**

An underemphasized role of S1 is related to the precision grip generation which is mediated via its connection with primary motor cortex. Studies (Davare et al. 2011; Hikosaka et al. 1985) involving inactivation of S1 in monkeys have demonstrated impaired prehensile activities such as difficulty in opposition and grip forces. Even though isolated inactivation could not be studied in humans, it has been observed that when the digits are anesthetized, coordination became impaired (Brochier et al. 1999). Zainos and colleagues (Zainos et al. 1997) found that after removal of S1, an animal could detect the stimuli but could not categorize stimulus speed. Few studies also have corroborated abnormalities in S1 in fraction of patients suffering from focal dystonia of hand. Bara-Jimenez and colleagues (Bara-Jimenez et al. 1998) documented degradation of the conserved organization of S1 in these patients along with expansions of finger representations in corresponding cortical centers. Studies (Harrison et al. 2013; Winship and Murphy 2009) in which stroke was experimentally induced in rodents, a shift in the somatosensory map was

observed. This was largely because neurons which were previously involved in integrating motor commands shift their roles and take minor roles in sensory processing (Wolpert et al. 1995).

A significant feature related to the S1 is the visual enhancement of touch, which potentially modulates the visual acuity (Taylor-Clarke et al. 2002). When the subject views the location where stimulus is being provided, then, the tactile acuity tends to improve and this might be due to some under emphasized cross modal interaction between visions and touch (Saal and Bensmaia 2014). The purported reason could be that viewing of the stimuli location improves the degree of representation of tactile space for that prescribed body part and this can be compared to visualizing using magnifying lens (Schaefer et al. 2005a). Thus, we could infer that S1 could function beyond just being a veridical station for peripheral inputs because of its ability to converge tactile perception and bodily representation, modulated by other inputs such as vision. Clubbing the sensorimotor integrative functions of the S1 along with the concept of widening of “body space” purported by the visual enhancement of touch, we could infer that a potential feed-forward model operates over there by combining the sensory consequences of the intended motor command and predicted motor outcomes (Haggard et al. 2003; Schaefer et al. 2005b). Indeed the motor learning, which involves identification of the mismatch between the intended and real sensorimotor states and recalibrating by using necessary motor commands, is facilitated using S1 (Desmurget et al. 2009). Furthermore, integration of somatosensory information from both hands helps the primates to perform coordinated tasks and tactile based explorations. Few studies (Tommerdhal et al. 2006) have shown that finger stimulation of one hand might lead to altered perception of the contralateral side.

Somatosensory cortex also has a role in recognizing emotions. Adolphs and colleagues (Adolphs et al. 2000) documented that patients with lesions involving S1 had impaired ability in categorizing and rating the intensity of emotions.

The role related to somatosensory processing might presumably be due to the connection with amygdala. The empathic responses, which get induced on observing others' states (Straube and Miltner 2011), have associated sensory dimension (Keyesers et al. 2010). Upon recognizing the facial expressions (Adolphs et al. 1996) and self-generated emotions (Damasio et al. 2000), there is an associated activation of somatosensory cortices. In addition to the discriminatory component, the affective component which involves emotional processing involves synchronized action of orbitofrontal and primary somatosensory cortices (McGlone et al. 2007). For example, nociceptive stimuli usually evoke negative reactions such as punishment, whereas pleasant stimuli like caressing touch tend to evoke positive rewarding reactions (Rolls et al. 2003). When the stimuli are given subsequently, we try to preempt the outcome by comparing with previous experience. Sometimes, a mere thought regarding the experience is enough to make us imagine the prior outcome. To sum up, somatosensory cortex, containing conserved representations of the body, maintains the internal and external awareness states (Critchley et al. 2004) and this can be equated with interoceptive attention. Studies (Braun et al. 2005) using functional imaging have documented higher activation of somatosensory cortex when an individual starts bothering about the existing emotional state.

## Plasticity of Somatosensory Cortex

The somatotopic maps, even though being conserved for respective body surfaces, have mutable degrees of plasticity. This can be observed in conditions such as amputation, where the input coming to a restricted area gets lost. In due course of time, the restricted area becomes responsive to neighboring responsive surfaces. Ramachandran VS and colleagues (Ramachandran et al. 2010) did significant amount of research to found the cross activation of neighboring areas after a hand is being amputated. This induces a form of tactile

illusion which is referred as phantom limb (Ramachandran and Hirstein 1998). Amputees in such cases experience the touch to their face as local and referred sensation on the phantom hand which can be deemed as altered reference fields. In one of the models (Flor et al. 2006) developed for pain due to phantom-limb, it was observed that activation of afferents from the face and stump of missing limb elicited sensations in the perceptual areas of missing limb. But these sensations felt in the amputated limb is mostly painful (McCabe et al. 2005), which is plausibly due to the incongruent mismatch happening at different levels of sensorimotor pathway. In addition, expression of genes aiding in synesthesia helps in cross-activation throughout the brain, and in professionals such as pianists the expression is significantly higher.

In addition to the limited cortical reorganization, cortical neurons demonstrate significant degrees of axonal plasticity. After subcortical lesions, it was found that ascending projections from thalamus to sensory cortex were bypassing the lesion areas (Staudt et al. 2006) and reaching their destination in the post-central gyrus. This suggests that the sensory neurons which convey sensations from periphery to specified sensory areas are "committed" much earlier in developmental stages.

## Definition

The study of how primates acquire, process, store, and use information in their environment (Shettleworth 2010).

## Overview

Primate cognition is the study of cognitive processes in nonhuman primates (hereafter, primates). The distinction between cognitive processes and behavioral ones is not easy, but most researchers would likely agree that cognitive processes, as compared to behavioral ones, are characterized by higher flexibility (i.e., individuals flexibly perceive the situation and flexibly react to it, depending on their own goal), and involve some form of mental representation (i.e., individuals mentally assess the situation, by also relying on information sources other than direct perception; Tomasello and Call 1997). Therefore, cognitive skills allow individuals to flexibly respond to a situation according to their goals and based on their mental representation of the situation, thereby making complex decisions. However, disentangling cognitive processes from behavioral ones is not always an easy endeavor, as mental processes cannot be directly observed, and simple noncognitive processes can also lead to complex behavioral patterns (Shettleworth 2010; Tomasello and Call 1997). Moreover, perceptual, motivational, and motor mechanisms may also interplay with mental ones, making it hard to reliably infer mental

processes from the behavioral observation of animals. Therefore, some authors prefer to use a broader definition of cognition, referring to primate cognition as to the study of how primates acquire, process, store, and use information in their environment (Shettleworth 2010). This broader definition implies that cognition may also include perceptual and simple learning processes, as in this view mental representations are not required for a process to be considered cognitive. Given that mental processes are not easily inferred from behavioral observations, other researchers prefer to envision cognition as a distributed process, in which interactions between individuals (rather than mental processes) are the main object of study (see Johnson 2001).

The study of primate cognition dates back at least to Charles Darwin. Darwin was the first scholar known to describe cognitive processes as biological adaptations that humans may share with other primates, and whose evolutionary origins can be traced back by comparing species with each other (see Tomasello and Call 1997). After Darwin, however, the study of primate cognition remained largely unexplored for several decades. Brilliant exceptions include the work by Wolfgang Köhler and Robert Yerkes at the beginning of last century. Köhler was a psychologist who was mainly interested in the primate ability to spontaneously solve novel problems. In a series of seminal studies, for instance, he systematically assessed how captive chimpanzees use tools to access out-of-reach food, setting the agenda for many future studies on primate cognition. Robert Yerkes, in contrast, was more generally interested in the study of primate behavior, and with several of his scholars and associates, he conducted groundbreaking studies on many different topics, like spatial memory, cooperation, communication, and, especially, the effects of enculturation on the development of primate cognition. For a long time afterward, however, most researchers working with nonhuman animals followed a behaviorist or ethological approach, with little interest for cognitive processes and the study of primate cognition. Behaviorists like Harlow, for instance, were mainly concerned with the study of observable behavior and learning processes, while ethologists like Tinbergen and Lorenz were

mostly devoted to the study of innate behavioral patterns, and the evolutionary origins of these behaviors (see Shettleworth 2010; Tomasello and Call 1997). In the 1960s, the situation completely changed, thanks to the first field studies in wild populations and the implementation of new systematic studies, especially in the area of primate communication (see Tomasello and Call 1997). These studies converged in revealing unexpectedly complex behaviors, which were largely suggestive of the existence of mental representations and cognitive processes. Since then, the number of studies on primate cognition has been steadily increasing.

Historically, differences in cognitive skills across primate species have been typically interpreted in line with the existence of a *scala naturae*, with species being phylogenetically close to humans also having more complex cognitive skills. Nowadays, the notion of a *scala naturae* is completely outdated, and it is indisputable that complex cognition repeatedly and independently evolved in different taxa as a result of convergent evolution (see Shettleworth 2010; Tomasello and Call 1997). Therefore, most researchers have turned to a socio-ecological approach when studying primate cognition. The socio-ecological approach mainly views cognition as an evolutionary adaptation to the specific socio-ecological challenges faced by a species. Through an increase in their cognitive abilities, individuals may better deal with the socio-ecological conditions in which they live, and thus be selected for during evolution. However, phylogenetic relationships are still crucial to understand the evolution of cognition. For instance, if two species share a long evolutionary history, it is possible that their cognitive skills will be similar, simply because they share some cognitive traits that emerged in their common ancestor. Therefore, a phylogenetic approach remains crucial to account for the species' evolutionary history when testing other evolutionary hypotheses on the emergence of complex cognition.

According to the socio-ecological approach, ecological challenges have played a crucial role for the evolution of primate cognition. If individuals face complex ecological challenges while

foraging, these challenges may be more efficiently faced through the evolution of complex cognitive skills and thus, larger behavioral flexibility. Several authors have proposed different ecological challenges that might be linked to the emergence of complex cognitive skills. First, primate species feeding on sparsely and patchily distributed food items may require an extra processing capacity to predict when and where to forage (e.g., Milton 1981). Fruits, for instance, are spatially and temporally spread in the environment, and keeping track of them through space and time might require increased spatial memory. Therefore, a high degree of frugivory has been traditionally considered a good predictor of enhanced spatial memory in primates. In the same line, feeding on a highly nutrient diet might allow the evolution of larger brains (as brain tissue is metabolically expensive), which could in turn be linked to enhanced cognitive skills. Second, dietary complexity, as assessed in terms of dietary breadth (i.e., the number of dietary categories consumed by a given species), may be linked to the evolution of complex cognition. Primate species with larger dietary breadth, for example, might be more likely to exploit novel food sources and might have thus evolved enhanced cognitive skills to better cope with this variation. In primates, there is indeed evidence that species with larger dietary breadth also have more complex cognitive skills, at least in some domains (e.g., MacLean et al. 2014). Third, extractive foraging (i.e., the ability to process plants, open nuts, dig insects, and use tools to access embedded food) might be linked to higher hand and hierarchical coordination, better understanding of means–ends relationships and increased propensity for social learning (e.g., Parker and Gibson 1977). Finally, predation may also represent an important selective pressure for the evolution of complex cognitive skills. When facing a higher predation risk, primates may evolve specific strategies to enhance their survival, including better communicative skills and the ability to more quickly classify predators and more effectively warn group members about danger as compared to species facing lower predation risks (e.g., Seyfarth et al. 1980). These skills may be especially enhanced in closed (and mixed)

habitats, where predators may be harder to detect (and cognitive and communicative skills might be especially needed).

Other authors, however, suggest that social challenges may be a stronger selective pressure for the evolution of complex cognitive skills in primates. When social life is complex, individuals need to use flexible cognitive strategies to recognize others; keep track of their relationships; and predict, coordinate, and manipulate their behavior (e.g., Humphrey 1976). In contrast to objects, social partners are reactive, unpredictable, and might respond with different behaviors to individuals' actions. Therefore, social complexity might posit higher cognitive challenges than ecological complexity, and could be a stronger selective pressure for the evolution of cognition. To date, there is yet no consensus on how social complexity should be defined. First, some authors have proposed social group size as an index of social complexity linked to enhanced cognitive skills (Dunbar 1998). However, group size does not necessarily correspond to the number of individuals in a group, and effective group size (i.e., the mean number of partners with whom individuals socially interact) might be a better measure of social complexity. Second, other scholars have argued that both group size and effective group size are a crude measure of social complexity, as social complexity would rather depend on the quality of social interactions. More explicitly, it would not be species living in larger social groups to show enhanced cognition, but rather species living in social groups with a higher frequency of complex social behaviors (Kudo and Dunbar 2001). Third, other researchers have defined social complexity in terms of fission–fusion dynamics. In particular, individuals living in groups that frequently split in subgroups of varying size and composition might need specific cognitive skills to better cope with the specific social challenges they face (e.g., enhanced memory to remember absent individuals, higher analogical skills to deal with fragmentary information about group members that are temporarily absent, higher inhibitory skills to adapt to continuous changes in group size and composition; see Aureli et al. 2008). Fourth, primates engaging in

monogamous pair-bonding might also require higher cognitive skills than primates living in larger cohesive groups, to better establish and coordinate complex behaviors with their partner (Dunbar 2009). Dunbar's original hypothesis mainly referred to monogamy in terms of sexual behavior, but this hypothesis is usually extended to predict that social complexities (and thus cognition) are higher if individuals preferentially interact with one or few partners, as individuals need to complexly coordinate behavior with few valuable partners.

Clearly, the list of evolutionary hypotheses presented here is not exhaustive. Moreover, different hypotheses are not necessarily mutually exclusive, because multiple selective pressures might independently but simultaneously act on different cognitive skills. In line with this, not all evolutionary hypotheses make the same predictions in terms of the cognitive skills involved. While some hypotheses predict an overall enhancement in cognitive skills, others only predict an enhancement in specific cognitive skills, assuming a certain degree of mind brain modularity. Indeed, cognitive skills across different domains are not always correlated with each other (see Shettleworth 2010). Therefore, direct comparisons of multiple primate species are essential not only to test evolutionary hypotheses about cognitive evolution, but also to understand the extent to which different cognitive skills are related to each other across individuals and species. Moreover, the relationship between cognitive skills and brain size is not straightforward. Brain tissue is highly costly in energetic terms, and can thus only be maintained if it provides adaptive advantages (Aiello and Wheeler 1995). In humans, brain size positively correlates with general intelligence, but in other species, there is little experimental evidence confirming this relationship. In primates, for instance, relatively larger brains are associated with a better ability to learn and innovate (e.g., Reader and Laland 2002). However, there is to date no consensus yet on the brain measures that can best serve as proxy for complex cognition. Some authors, for instance, use absolute brain size as a proxy for cognitive skills, while others maintain that

relative brain size, encephalization quotient (i.e., the ratio between observed and expected brain size), or number of neurons are more precise measures of cognition.

Besides differences across species, primate cognition may also be characterized by important intra-specific variation. Intra-specific variation in cognition can happen at different levels, including variation across individuals belonging to the same group, and/or across conspecific groups and populations (Strier 2016). Within the same group, for instance, individuals may show different cognitive skills depending on their age, as some cognitive skills require some time to develop during infancy, and/or may decrease when individuals become older. Across groups, moreover, cognitive differences may result from genetic variation (e.g., if groups belong to different populations) or from differences in the socio-ecological conditions in which individuals grow up, as the socio-ecological challenges experienced through life might also affect the emergence of cognitive skills. Along this line, one central aspect for the study of primate cognition is the possibility that individuals living in captive groups, which are commonly used as study subjects in cognitive studies, may importantly differ in their cognitive skills from their conspecifics living in the wild. Captive primates experience atypical living conditions during their ontogeny and, according to some authors, they might therefore develop unique cognitive skills, thus limiting or even hindering any generalization to wild primates (Boesch 2021). In particular, socio-ecological constraints experienced during life history, continuous exposure to human cultural milieu, lack of predation risk and high exposure to novel objects in captivity might all affect the development of cognition, preventing captive primates from being representative models for the study of cognition. However, studies in captivity provide essential information on the cognitive potential of a species, and allow to systematically control for the effect of several confounding factors in a way that is often not possible in the wild (Tomasello and Call 2008). Therefore, the study of cognition in both wild and captive settings should be viewed as necessary and

complementary for a thorough understanding of primate cognition.

Traditionally, the study of primate cognition has been divided into the study of physical and social cognitive skills (e.g., Shettleworth 2010; Tomasello and Call 1997). At first sight, this division might appear arbitrary, because several cognitive skills used in the physical domain are likely also used in the social domain, and the other way around. However, the traditional distinction between physical and cognitive skills is useful to differentiate between skills that most likely evolved in the foraging context (i.e., physical cognitive skills) and those that probably emerged as a response to the specific social challenges faced by a species (i.e., social cognitive skills). This approach is in line with a modular or partly modular view of cognition, according to which cognitive skills, at least to a certain extent, consist of specialized modules that evolved rather independently from each other, reflecting adaptations to specific socio-ecological problems. Although other scholars emphasize how individual cognitive skills often correlate with each other, with most of the variance across domains being accounted for by a single factor (i.e., G, or general factor of intelligence; see Plomin 2001), it is likely that independent domain-specific modules coexist in the brain with a general factor of intelligence. In particular, while some properties of the brain (e.g., the amount of gray matter) may generally affect multiple areas of the brain, leading to correlations across domains, cognitive processes might be largely localized in discrete regions, so that individuals and species having better cognitive skills in some domains would not necessarily excel in the other domains. Therefore, the distinction between physical and social cognitive skills appears to be both practical and theoretically founded.

Physical cognitive skills include all those cognitive abilities that likely evolved in a foraging context, to more effectively locate, quantify, and process food. Among these skills, researchers usually identify the ability to understand objects and space, understanding of time, quantitative cognition, and causal and inferential reasoning (Shettleworth 2010; Tomasello and Call 1997). First, primates

generally show advanced cognitive skills in terms of object permanence. In particular, primates can successfully locate an object that has moved out of view, and most species have also shown the ability to follow visible and invisible displacements of objects across a variety of conditions (for a review, see Cacchione and Rakoczy 2017). Second, primates can effectively locate resources in their environment. Most species likely do it by using habitual routes that allow them to routinely monitor potential food sources, with little cognitive implications. However, other species might use cognitive maps to flexibly navigate through space, creating mental representations of their environment (Shettleworth 2010; Tomasello and Call 1997). Wild chimpanzees (*Pan troglodytes*), for instance, can approach food sources from multiple directions; they mostly travel in straight lines to reach food, and seem to have expectations about their distance to the food sources (Normand and Boesch 2009). Therefore, they appear to have a mental representation of their home range, relying on cognitive Euclidean maps to navigate through it. Third, primates are known to have relatively good short- and long-term memory. However, much less is known about their understanding of time and, in particular, about their ability to recall individual past events (see Lewis et al. 2019). Similarly, little is known about primate ability to plan future events, although some evidence suggests that at least great apes can plan ahead by, for instance, producing and gathering stones that they require for later use (e.g., Osvath 2009). Fourth, primates are proficient in making relative quantity judgments, reliably selecting the larger amount out of two discrete stimuli (i.e., food items) or even out of two continuous ones (i.e., liquids; for a review, see Beran 2017). Some species are also proficient in “summing” quantities by, for instance, preferring the container in which more food pieces have been inserted, one after the other. Moreover, some studies have tested whether primates show numerical cognition, by exclusively relying on numerical cues (e.g., number of items) rather than using more general nonnumerical cues (e.g., density or size) to select the larger stimuli. These studies have reliably shown that apes and monkeys can also make numerical judgments across a variety of conditions (see Beran 2017). Finally, primates have been tested with

different approaches to assess their understanding of means–ends relationships and causality (for a review, see Völter and Call 2017). A classic setup that has been used to test causality consists in presenting individuals with two strings, only one of which is attached to the food. If primates understand means–ends relationship, they should spontaneously select the string attached to food, regardless of the spatial disposition of the strings – a task that most species can proficiently solve, at least in the easier conditions. In order to assess their understanding of causal relationships, primates have also been tested with trap tasks and tool use tasks. In trap tasks, for instance, a food reward is placed in a Plexiglas tube with a central hole, and the food can be extracted only by moving it in the direction opposite to the hole, where otherwise the food disappears. Primate performance in these tasks is generally poor, unless the cognitive demands of the task are reduced (e.g., without requiring primates to use a tool; see Völter and Call 2017). In tool use tasks, instead, researchers can assess primate ability to flexibly use tools, and/or to select the most effective tools to obtain a reward, based on their functional properties. However, one should note that, when studying causality, it is often not easy to disentangle whether primates really establish causal relationships between stimuli (i.e., inferring the cause from the effect, or predicting the effect from the cause), or whether they simply learn to associate them through time.

Social cognitive skills include those cognitive abilities that likely evolved in a social context, to more effectively interact with others, predict and manipulate their behavior (see Humphrey 1976). One of the most basic social cognitive skills is the ability to acquire, process, store, and use social knowledge (Shettleworth 2010; Tomasello and Call 1997). Abundant evidence shows that primates have complex knowledge about third-party relationships (e.g., kin or rank relationships). For instance, many primate species show redirected aggression, behaving aggressively toward a previous aggressor's kin, thus suggesting that they recognize kin relationships between other individuals. Moreover, primates can classify group members according to different characteristics, simultaneously relying on multiple

information sources. These processes can rely on cognitive mechanisms (e.g., primates learn about third-party relationships through experience, they create mental categories for these relationships, and then generalize them to other contexts/pairs of individuals), although noncognitive explanations may also partly explain these processes (see Shettleworth 2010).

Depending on the species, primates also appear to have second-order intentionality; i.e., they do not only have intentional states (e.g., knowledge, desires, and beliefs; first-order intentionality), but also understand that others have intentional states, which might differ from their own ones (see Shettleworth 2010; Tomasello and Call 1997). Sometimes, researchers also refer to this ability (or to a subset of these abilities) with the term “theory of mind,” or “mental state attribution.” These abilities might be evolutionarily advantageous to more effectively interpret, predict, and manipulate others' behavior, in cooperative and competitive contexts (see Dunbar 1998; Krupenye and Call 2019; Shettleworth 2010; Tomasello and Call 1997). Through the years, several studies have tested whether primates show “theory of mind.” However, it is often hard to disentangle whether primates really understand others' mental states, or whether they are rather inferring them from the observation of others' behavioral cues (for a discussion, see Krupenye and Call 2019). Several studies have shown that primates are sensitive to others' visual (and auditory) perspective, and understand others' attentional state. Apes and monkeys are sensitive to others' gaze, they know what others can and cannot see, and use this knowledge to adjust their behavior. Primates, for instance, follow others' gaze around barriers, more likely use visual gestures when being in the partner's visual field, and/or after entering it, and in a competitive context they prefer to reach for a food that other group members could not see (for a review, see Krupenye and Call 2019).

Moreover, abundant evidence shows that apes and monkeys can understand others' goals and intentions. Primates, for instance, behave differently to humans that failed to share food with them because they were impeded, as compared

to those that did not want to do it. According to some studies, some primate species are also able to understand others' goals and accordingly help them (see Krupenye and Call 2019; Shettleworth 2010; Tomasello and Call 1997). For a long time, however, researchers could not find experimental evidence that primates also understand others' beliefs. In particular, apes failed to use others' false beliefs to maximize their food intake across several studies (see Krupenye and Call 2019; Tomasello and Call 1997). These results were in line with the idea that understanding false beliefs may be especially demanding, by requiring primates to create and maintain two conflicting mental representations: one of their own view of the world, and one of the other individual's view. In the last years, however, the use of novel technologies has allowed researchers to also demonstrate understanding of false beliefs, at least in great apes. By using eye-tracking procedures, researchers could show that apes understand others' false beliefs, anticipating where others would search if they had a false representation of reality (see Krupenye and Call 2019).

Furthermore, the study of social cognition has also included the assessment of primate prosocial skills (i.e., behaviors performed to alleviate the needs of other individuals or to improve their welfare, without the actor necessarily incurring extra costs to provide these benefits). In some primate species, individuals cooperate with each other by hunting in group, rearing infants together, forming coalitions, or sharing food, but these complex behaviors do not necessarily require cognitive skills to unfold. Some of the tasks used to study prosociality in primates have investigated the exact motivations underlying prosocial behavior (e.g., inequity aversion). Other studies, however, have focused on the cognitive underpinnings of cooperation (e.g., understanding each other's role, understanding of others' goals and intentions).

Another area of great interest in primate social cognition is social learning. Social and cultural learning allow the transmission of knowledge and skills across individuals and generations, respectively, and are thought to have played a crucial role for the evolution of human cognition

(see Cacchione and Amici 2020, for a review). To date, social learning is known to be widespread across a variety of taxa, but more complex forms of social learning, like imitation and culture, are likely much less common. In humans, imitation and cultural learning usually rely on complex cognitive underpinnings, like shared intentionality and shared experiences, whereas in other primates these forms of social learning likely unfold in cognitively less complex ways (see Cacchione and Amici 2020). Finally, researchers working on social cognition have also devoted special attention to primate communication. With regard to vocal communication, for example, some species are known to use specific alarm calls depending on the predator approaching, they appear to vocalize intentionally, and can even take other group members' knowledge into account when informing them about the presence of danger (see Cheney and Seyfarth 2018, for a review). Moreover, primates anticipate how listeners will respond to their calls, and may also eavesdrop when others vocalize, suggesting high flexibility in vocal communication and likely complex social cognitive skills.

Despite clear advances in the study of primate cognition, also thanks to the use of new technologies, there are still several problems that affect this research area. First, as we briefly outlined above, it is often hard to exclude alternative lower-level behavioral explanations to seemingly cognitive phenomena (e.g., Povinelli 2020). Well-thought experimental approaches can surely help to address this issue, but gathering conclusive evidence on the cognitive underpinnings of a behavior is often not easy, especially when using an observational approach. Similarly, it is not always easy to disentangle individuals' cognitive performance from other confounding factors (like motivation or perceptual skills; see, e.g., Schubiger et al. 2020). Second, and in line with this, cognitive studies usually include very few individuals. This is often unavoidable due to logistic constraints and low availability of study subjects. However, the inclusion of few individuals clearly poses a serious problem to the study of primate cognition due to the important intra-specific variability that exists in primate behavior

and cognition. Primates, for instance, might show a different performance in cognitive tasks (and/or have different cognitive skills) depending on their sex, age, rank, personality traits, and/or life histories. These differences may be especially relevant across wild conspecific groups (which often experience different ecological challenges), but they may also be present across captive primate groups, depending on the living conditions across study sites. Such a high intra-specific variation has likely contributed to the lack of reproducibility that unfortunately characterizes much cognitive research and general research in psychology (Open Science Collaboration 2012). Third, studies on primate cognition are still often focused on very few species. Clearly, this also largely depends on practical considerations. In captivity, some species are simply not present, and in the wild, it might simply be hard to come up with cognitive tasks that fit with the peculiar socioecology of the species (e.g., nocturnal primates). However, failure to include more primate species might lead researchers to reach wrong conclusions. For instance, it is possible that some cognitive skills are more widespread than actually thought, but that researchers have not yet identified the right target species. Finally, most studies in primate cognition have been conducted in captivity, by isolating individuals from their social groups. This approach has clear benefits, in that it often allows to optimally control for the effect of some confounding factors (e.g., competition in the group). However, some researchers suggest that isolating individuals from their social groups might affect their cognitive performance, and that cognitive tasks should ideally be planned to allow testing in a social setting, thus also increasing their ecological validity (Cronin et al. 2017).

## Primate Communication

Katja Liebal

Department of Education and Psychology,  
Comparative Developmental Psychology, Freie  
Universität Berlin, Berlin, Germany

## Introduction

Communication is defined in very many ways. Biological approaches often emphasize that communication is mediated by evolutionary shaped signals (Krebs and Davies 1993), selected for the purpose of communication and the receivers' ability to successfully decode such signals. Some definitions differentiate between non-behavioral and behavioral communication, with the latter not considering invariant displays, such as fur coloration, as means of communication (Smith 1977).

Psychological approaches, on the other hand, focus more on the cognitive mechanisms underlying communication, with central interest in the question whether the actor uses specific signals intentionally to influence others' behavior. Since intentional use is one of the key characteristics of human language, research on primate communication is often motivated by an interest in the origins of human language. By comparing the communicative systems of humans and non-human primates, scientists aim at identifying potential precursors to human language in our closest relatives, the nonhuman primates. As a result, research into primate communication might focus more on cognitive processes than research into other animals' communication.

However, *which* aspects of primate communication are investigated very much depends on

the signal type or “modality.” To communicate, primates use a variety of different sensory channels – olfaction, touch, vision, and audition. Since olfaction has hardly been studied with regard to its cognitive foundations, only facial (visual), vocal (auditory), and gestural signals (tactile, visual, auditory) will be considered for the purpose of this entry. In the next section, the different signal types are defined, followed by a summary of different evolutionary scenarios, each suggesting a different modality as the potential origin human language. Finally, an overview of research into primate communication is provided, to demonstrate which features are studied as potential precursors of human language. However, this overview is not exhaustive, as it can only provide glimpses at the rich body of existing studies. Most importantly, the aim is not to argue in favor or against any theory of language evolution but to highlight that research foci differ in vocal, facial, and gestural research, which hinders systematic comparisons across these modalities, and as a result, impede a multimodal approach to studying the origins of human language.

## Defining Signal Types

The classification of different signal types is often confusing. Most signals are not “pure signals” with regard to their sensory modality, since they can rely on more than one sense. For example, a gesture can convey information via different sensory channels, like the gorillas’ “chest beat,” which produces an audible sound together with a visible movement. Furthermore, the production of one signal type might be inextricably tied to another signal type. For example, producing a “scream” vocalization is linked to the specific “scream face” expression. Finally, gestures comprise signals of different modalities, including visual, tactile, and auditory signals. Thus, different signal types are not always differentiated based on their sensory modality but might be rather categorized based on the different cognitive mechanisms assumed to underlie their usage (Liebal et al. 2013).

Primate **gestures** are considered voluntarily produced, purposeful behaviors, directed at specific individuals to influence their behavior (Leavens et al. 2005). They not only comprise different sensory modalities (visual, tactile, auditory), but they can also be produced with different body parts, such as the limbs (“offer arm”) or the head (“head bob”), and they may involve movements (“slap”) but also postures (“present”). Visual gestures, like “extend arm” or “present,” are distant signals and, in addition to manual gestures, may also include body postures and head movements, but not facial expressions. Tactile gestures, such as “slap” or “gentle touch,” involve the physical contact between two interacting partners. Auditory gestures produce a sound with different body parts, such as “hand clapping” or “chest beat,” but unlike vocalizations, they do not engage the vocal cords in the production of the sound (Call and Tomasello 2007). In contrast to auditory gestures, **vocalizations** (or calls) emerge from the vibration of the vocal folds within the larynx. They should be differentiated from sounds, such as “lipsmacks” or “raspberries,” which are also auditory signals, but they do not engage the vocal cords. Vocalizations are graded signals, which can vary in their structural properties, such as frequency, amplitude, and temporal pattern. **Facial expressions** are also graded signals, and are defined in different ways. While some refer to them as “facial gestures” (Maestripieri 1999), others consider facial expressions a separate signal type than visual gestures, although though both are visual signals. Finally, some specifically focus on orofacial movements to study communicative mouth movements like “teeth chatter” or “lipsmacks.”

## Origins of Human Language

There numerous scenarios suggesting how language might have evolved. While comparative researchers agree that precursors to human language, including neurobiological substrates, anatomical structures, or cognitive skills, are shared

with other primates, they are at odds with regard to the modality from which language might have evolved.

For example, researchers proposing a **gestural origin** of human language suggest that our ancestors initially communicated by using voluntarily produced manual gestures, with spoken language evolving on top of this visual communication system (Hewes 1973). This is supported by the close link between gestures and spoken language, since gestures (in addition to facial expressions or vocalizations) remain to be an integral part of human communication, even if humans possess a fully fledged language (Kendon 2004). Research into developmental pathways of humans shows that before infants start to produce their first words, they already use a variety of gestures, such as showing or pointing to objects (Iverson and Goldin-Meadow 1998). Further support for a gestural origin is provided by the discovery of mirror neurons, which are active both when an individual performs and perceives a specific action, such as manual grasping movements or communicative mouth movements (Rizzolatti and Arbib 1998). Thus, the finding that the corresponding brain area in nonhuman primates seems to be a homologue of Broca's area in humans indicates the evolutionary close link between manual actions and language production.

On the other hand, proponents of a **vocal origin** of human language argue that because speech is using the acoustic channel, language most likely emerged from the vocal abilities of our ancestors (Cheney and Seyfarth 2005; Zuberbühler 2005). In support of a vocal origin, they highlight that there is evidence for both referential (semantical) and syntactical structures in vocalizations of nonhuman primates. Thus, they use functionally referential calls, which seem to refer to specific objects or events, and combine single vocalizations into meaningful, sometimes rule-governed sequences.

Only few theories suggest a **facial origin** of human language. However, orofacial movements receive increasing attention, since one of the major shortcomings of gestural theories is that they are not providing convincing explanations

for the transition from visual, gesture-based communication to vocal, spoken communication (Wacewicz et al. 2016). Thus, orofacial movements may represent the evolutionary link between visual gestures and acoustic utterances, since they convey both visual and auditory information. Furthermore, like manual gestures, orofacial movements are voluntarily produced. Thus, language might have evolved directly as speech from previously non-communicative ingestive mouth movements to a flexible repertoire of syllables in a way that these "...ingestion-related cyclicities of mandibular oscillation (associated with mastication [chewing] sucking and licking) took on communicative significance as lipsmacks, tonguesmacks, and teeth chatters..." (MacNeilage 1998, p. 499).

Together, this section shows that researchers favor different modalities to explain the evolution of language and, consequently, investigate different aspects of primate communication. The following section will summarize the current knowledge for each modality with focus on those findings from comparative research on primate communication relevant for the understanding of language evolution.

## What Do We Know About Primate Communication?

A review of existing studies on primate communication, covering almost 60 years up to the year 2008, impressively demonstrated that our knowledge varies drastically across modalities and primate taxa (Slocombe et al. 2011). For example, two thirds of the total of existing studies ( $N = 553$ ) focused on vocalizations, one fifth on facial expressions, and only 9% on gestures. The majority of vocal research investigated different monkey species, while gesture research almost exclusively focused on great apes, with an apparent lack of gesture research investigating populations in their natural habitats. With regard to the methods used to explore them, experimental approaches are commonly applied to study vocalizations, while observational methods are mostly

used to study gestures and facial expressions. This again shows that there are considerable gaps of knowledge in primate communication and that results are difficult to compare across modalities and species. Most importantly, however, research into primate communication is almost exclusively unimodal, focusing on only one modality at the time. Therefore, with very few exceptions, very little is known about if and how different modalities are combined and how they influence each other.

### Gestures

While classic studies investigated gestures as elements of a species' behavioral repertoire, more recent studies focused more on the psychological aspects and, in this context, the cognitive mechanisms underlying gestural communication (Call and Tomasello 2007). Not only do gesture studies mostly consider great apes, many of them investigate chimpanzees, in both captive and natural settings. Little is known about small apes and monkeys, except for few macaque and baboon species, and there are virtually no studies investigating if New World monkeys or lemurs use any gestures at all. Since most of gesture research is conducted in captive settings, it is currently unclear whether the repertoires found in captive apes are also representative for wild populations. Furthermore, the total number of gestures reported for a given species may vary across studies, because researchers use different methods of data collection or different measures for discriminating between gesture types. For example, the number of gorilla gestures described in several publications varies between 30 and 100, indicating that it is rather difficult to compare findings across different studies.

### Variability of Gestural Repertoires

To highlight the flexibility of the primate gestural communication, much attention has been paid to the variability of gestural repertoires across individuals, age groups, or populations, as well as to different mechanisms of gesture acquisition. Thus, a considerable degree of variability indicates that – unlike in the case of vocalizations or

facial expressions – new gestures can be acquired and/or already used gestures can be modified over an individual's lifetime.

Considering the variability of individual gestural repertoires, most is known about great apes and siamangs, one species of small apes. Across species, gestural repertoires increase with age but decrease again in adults. Thus, many gestures are used during play, but since this context is of less importance for adults, they consequently use fewer gestures. In general, there are only few reports for group-specific gestures, which are used by the majority of individuals of one group, but not in another one. In such cases, it is important to exclude the alternative explanation that specific housing conditions in captivity or ecological factors in natural habitats are responsible for the emergence of group-specific gestures. Some gesture studies report the use of idiosyncratic gestures, which are used by single individuals only, while other researchers point out that such findings might be the result of too short observational periods, which are not sufficient to capture complete gestural repertoires. Together, findings indicate that, while individual repertoires may vary over lifetime, overall, there is only limited variability across different groups and within a species.

Some researchers take this even further and argue that also across great ape species, there is very little variability between their gestural repertoires, suggesting that they are species-specific and most likely genetically determined (Genty et al. 2009). Others suggest that gestures are shaped in repeated social interactions and via this process of ontogenetic ritualization, gestures emerge from previously non-communicative behaviors (Tomasello et al. 1994). This is based on the findings that repertoires vary considerably across individuals and age groups and that specific gestures might be shaped in repeated interactions within dyads, such as initiations of "carries" in bonobo mother-infant dyads. Note that up to date, only very few studies use a longitudinal approach to study gesture acquisition over the first years of life in nonhuman primates. From the little we know, it seems that at least in great apes, both genetic transmission and social factors shaping

communicative behaviors are involved in the acquisition of gestural repertoires.

### Intentional Use

Primate gestures are, by definition, intentionally used signals. A variety of different markers of intentionality are applied across studies, including the social use of a signal in the presence of an audience, accompanying visual orienting behavior or gaze alternation, the adjustment to the recipient's attentional state including the use of attention-getting behaviors, as well as persistent and elaborated gesture in case of the failure of communicative attempts (Leavens et al. 2005). However, there is little agreement with regard to which and how many of these markers should be considered to decide if a given behavior is produced intentionally (Liebal et al. 2013). In the following, some of the main findings regarding each of these criteria are briefly summarized.

The *social use* of gestures has been mostly studied in experimental settings. Great apes or monkeys request food from a human experimenter in varying conditions, with the experimenter present or absent, and/or visually attending or not attending. These studies showed that both monkeys and apes use gestures only in the presence of an audience.

*Visual orienting behavior*, and specifically eye contact or gaze, is a measure used to identify if a gesture is directed toward a specific individual. However, given the lack of a white sclera in most of the nonhuman primate species, for the human observer, it is often impossible to reliably decide if eye contact is established or not. Therefore, some studies use a related measure, *gaze alternation*, with the gesturing individual repeatedly gazing between the recipient and another such entity, such as another individual, an object or a location (Leavens and Hopkins 1998). Note that this measure is only applicable for triadic interactions, which in addition to the gesturer and recipient also involve a third entity. However, this only applies to few of the gestural interactions of non-human primates.

The *adjustment to the recipient's attentional state* is well studied across a variety of ape and monkey species (Call and Tomasello 2007). In

interactions with either conspecifics or a human experimenter, they only use visual gestures if the recipient is visually attending. If the recipient is not attending, however, they rarely use gestures to attract the other's attention, at least in interactions with conspecifics. In experimental studies with humans, results are more mixed, with some studies reporting that great apes use attention-getting behaviors, such as auditory gestures, in case the human is present, but not oriented toward them, while other studies failed to confirm this. Similarly, some experimental studies showed that in more complex settings, with more than one experimenter present confronting the ape with varying attentional states and body orientations, apes were less sensitive to the human's attentional state (Povinelli and Eddy 1996). It seems that different information is conveyed by the orientation of the face and body, respectively, in a way that the face indicates the recipient's attentional state, while body orientation implies whether the human is able to deliver any food or not (Kaminski et al. 2004).

If communicative attempts fail, gesturers may either *persist* and continue to use the same gesture, or they may even *elaborate* their gesture use by using a different, more efficient gesture to elicit the recipient's response. The corresponding studies, mostly conducted with apes, have produced mixed findings. While chimpanzees repeat the same gesture to get the recipient to respond, gorillas and orangutans may also continue to gesture but independently of whether the recipient responded or not. For interactions with humans, there is evidence that both chimpanzees and orangutans elaborate their gesture use in case the human does not respond or not respond appropriately (Cartmill and Byrne 2007), while for interactions with conspecifics, this pattern could not be confirmed.

To summarize, intentional use is a central topic in primate gesture research, as are variable repertoires and their flexible usage. However, definitions of the term "gesture" as well as the type and number of criteria used to identify intentional use may drastically vary across studies. Most studies focus on captive great apes and find substantial evidence for flexible usage of gestures, while

research on the variability between individual repertoires produced mixed results.

### Vocalizations

Since many primate vocalizations are graded signals, it is often difficult to determine the exact number of calls of a species' vocal repertoire. It is therefore difficult to compare the size of vocal repertoires across species. However, the size of vocal repertoires seems to be correlated with group size, indicating that more complex social structures require a more varied communicative repertoire (McComb and Semple 2005).

### Variability and Flexibility in Vocal Repertoires and Their Usage

Isolation studies showed that despite the lack of contact to other conspecifics, monkey infants start to produce their species-specific vocalizations. Similarly, cross-fostering experiments have demonstrated that monkey infants, raised by another species, still produce the species-specific vocalizations of their own species (Owren et al. 1992). This strongly suggests a genetic determination of primate vocalizations, resulting in "closed" repertoires with little potential to acquire novel vocalization. However, there is increasing evidence that the structure of primate vocalizations can be modified, for example, by social factors, indicating more flexibility than previously assumed. For great apes, the acquisition of novel sounds like "whistles" in orangutans or "raspberries" in chimpanzees has been reported (Hopkins et al. 2007). However, it is important to note that unlike vocalizations, these sounds are not produced by using the vocal folds. This indicates that primates have control over articulators such as their lips and tongue, but not their larynx.

Higher degrees of flexibility are reported for the *usage* of vocalizations. Some species only produce food calls if an audience is present or even only in case specific individuals are in close proximity. Similar findings have been reported for other social contexts, such as sexual or territorial behavior, suggesting that primates adjust their call production not only to the presence/absence but also to the composition of the audience.

### Referential Vocalizations and Meaningful Combinations

In human language, many words are referential, because they refer to specific entities in the world. Therefore, comparative researchers are specifically interested in context-specific vocalizations "... to find the animal equivalent to referential words in human language" (Liebal et al. 2013, p. 399). Of particular interest are "functionally referential vocalizations," which are reliably produced in response to a specific stimulus, with recipients responding to this vocalization even in the absence of the eliciting stimulus, in the same way they would respond when the eliciting stimulus would be present. Most of this research was conducted with monkey species, such as vervet monkeys and Diana monkeys, with referential vocalizations reported for different contexts including the discovery of predators or food. One of the first studies describing the use of referential vocalizations found that vervet monkeys in east Africa use specific alarm calls depending on which of their main predators – eagles, pythons, or leopards – they encounter. Playback experiments then demonstrated that these predator-specific calls also elicit a predator-specific response, similar to the response they would show if the predator would be present (Seyfarth et al. 1980). Since then, different alarm call systems have been reported for many primate species, but many of them are less specific. For example, some species differentiate between aerial and terrestrial predators, but not between predator types, and/or they may also consider contextual information in addition to the call itself. In the feeding context, vocalizations refer to the presence of food, in similar ways like alarm calls indicate the presence of a predator. Food calls may also vary in their specificity, and either announce the presence of (large quantities of) food, or may differentiate between different food values. In some cases, calls might even refer to specific food types. Functionally referential vocalizations have also been reported for other social contexts, such as sexual behavior, in different macaque species, bonobos, and chimpanzees. Acoustically different calls during copulations may vary as a function of the females'

reproductive status, the outcome of a copulation (resulting in an ejaculation or not), or the sex and rank of the interacting individuals. However, some of these findings are still debated, since playback experiments are needed to confirm that these acoustically distinct calls are indeed meaningful for the recipients.

The concept of functionally referential vocalizations has been recently criticized, as to successfully understand the information conveyed by some signal, it must be specific to at least some extent. Therefore, it has been suggested that seemingly referential vocalizations are qualitatively not different from other signals (Wheeler and Fischer 2012). However, despite this criticism, functionally referential vocalizations are still intensively studied across different primate species.

Since another key feature of language is the *duality of patterning*, which enables the combination of a finite number of (meaningless) components into a potentially infinite number of meaningful utterances, comparative researchers aim at identifying similar structures in vocal (and also gestural) sequences. Thus, researchers are interested in the question whether nonhuman primates combine vocalizations into longer sequences to create new meanings or at least use these combinations differently than the corresponding component calls.

Some vocalizations, when combined with others, function as modifiers, since they change the meaning of following vocalizations. For example, Campbell's monkeys combine their functionally referential "eagle"- or "leopard"-alarm calls with another, preceding "boom"-call in situations that are less dangerous (Zuberbühler 2002). This species also combines its six distinct loud calls into sequences, which are then used in specific contexts only, and may thus represent instances of combinations which are used for new functions. Putty-nosed monkeys do not use predator-specific alarm calls, but they produce sequences consisting of "hack" and "pyow" vocalizations, which are given in response to many stimuli. They are more likely to use "hack"-sequences in response to eagles and "pyow"-sequences in response to leopards.

Interestingly, they combine these two different calls into a "pyow-hack" sequence in situations when they want to initiate group travels and therefore convey a new message by combining these different vocalizations (Arnold and Zuberbühler 2006).

Together this section shows that while there is limited flexibility in the production of vocalizations regarding the modification of their structural properties and the acquisition of novel vocalizations, there is a considerable degree of flexibility in the usage of vocalizations. Thus, unlike gestural signals, vocalizations are combined into meaningful sequences, which further increase the flexibility of an otherwise "closed" vocal repertoire with only a finite number of elements.

### Facial Expressions

Primates have very mobile faces and can change the appearance of their faces, by moving the jaws and lips, eyelids, and ears. Such facial movements are often referred to as facial expressions. Many facial expressions are commonly used across many primate species, and some are limited to few species only (van Hooff 1967). Facial expressions of nonhuman primates are often considered stereotypical displays and are investigated in an evolutionary framework to study their adaptive function, with focus on the receiver of such displays. On the other hand, very little research considers proximate aspects of facial communication, such as the intentional and flexible usage of facial expressions or the mechanisms underlying their acquisition. To disentangle the evolutionary origins of language, however, comparative researchers dedicate their attention to orofacial movements and specifically the rhythmic patterns of mouth movements during ingestion or communication. Therefore, this entry will focus on these aspects of facial communication.

### Rhythmic Patterns of Primate Mouth Movements

The production of vocalizations is often inextricably linked to facial movements, particularly the lower part of the face. Researchers focus on such communicative mouth movements, since they are interested in the extent of control over such orofacial movements and the interplay of the

vocal and visual modality, specifically how recipients integrate such multisensory information.

Research on communicative mouth movements of monkeys showed that their vocalizations have a similar acoustic rhythmicity like human language, but unlike humans, monkeys lack the concomitant rhythm of the facial movement (Ghazanfar and Takahashi 2014). However, geladas produce lipsmacks together with a “wobble”-vocalization. Interestingly, the rhythm of the mouth movements during these vocalized lipsmacks resembles that of human language (6–9 Hz), which has been interpreted as evidence for the hypothesis that lipsmacking represents a precursor to the emergence of human language (Bergman 2013). Interestingly, the movements of the involved articulators (lips, tongue, hyoid) differ depending on whether monkeys produce a communicative (e.g., lipsmacks) or ingestive (e.g., chewing) mouth movement: only during the production of communicative lipsmacks, the corresponding anatomical structures move with a speech-like rhythm.

Regarding the perception of such orofacial movements, rhesus monkeys seem to prefer lipsmacks produced within the species-typical range of approximately 6 Hz but pay less attention when the rhythm is experimentally perturbed. Concerning the cross-modal identification, both monkeys and great apes recognize the auditory–visual correspondence between their different vocalizations and the corresponding facial movements. Furthermore, crested macaques show an increased probability of affiliative behavior in response to those lipsmacks that consist of both visual and auditory components compared to when lipsmacks only consist of a visual component (Micheletta et al. 2013).

#### Intentional Control

Another major argument for orofacial movements representing the evolutionary origin of language is that primates seem to have voluntary control over their production like found for manual gestures, but not vocalizations (Corballis 2002). Like in humans, the size and structure of the neurobiological substrates innervating facial muscles of great apes indicate the greater differentiation of muscles involved in the production of facial

expressions and the increased voluntary control over the production of orofacial movements (Sherwood et al. 2005). Interestingly, at least in rhesus monkeys, the coordination of facial muscles seems to differ between different types of rhythmic orofacial movements. While a rhythmical coordination of those muscles innervated by the facial nucleus has been found for the production of communicative mouth movements such as lipsmacks, this was not the case for ingestive mouth movements (Shepherd et al. 2012). This finding provides further support for the hypothesis that specific orofacial movements – with a communicative function – might have played an important role in the emergence of human language.

Together these findings suggest that multisensory integration of visual and auditory information is an integral part of primate communication. Furthermore, this close link between auditory and visual information in communicative mouth movements, their speech-like rhythm and their intentional production, seem to provide support for the hypothesis that language might have evolved through the modification of rhythmic facial movements in ancestral primates.

## Conclusion

This chapter demonstrated that in searching for the origins of human language by studying the communication of nonhuman primates, research foci differ across the gestural, vocal, and facial modality. While gestural researchers focus on different markers of intentionality and flexibility in gesture usage, vocal research centers on the referential use of vocalizations and their meaningful combinations. Facial researchers, on the other hand, are mostly interested in the rhythmical patterns of orofacial movements and their interplay with vocal utterances.

In the ongoing debates about language origins, researchers often focus on *one* specific modality only and list the arguments why the corresponding other modalities are not suitable candidates to explain how language might have emerged. Researchers supporting theories of a vocal origin highlight that primate vocalizations refer to

external entities and are combined into meaningful sequences, while these two features seem to be absent in the gestural domain. Gesture researchers, on the other hand, emphasize that unlike vocalizations and facial expressions, gestures are intentionally and flexibly used across several contexts and that repertoires vary across individuals, groups, or age classes. In contrast, primates seem to have little control over the production of their vocalizations and facial expressions, there is very limited variability among individual vocal or facial repertoires, and they do not acquire new signals during ontogeny, resulting in rather constrained or closed repertoires. Gesture researchers therefore argue that because of the lack of intentional use, invariable repertoires, and limited flexibility in the production of both facial expressions and vocalizations, language most likely did not emerge from a vocal or facial but gestural origin.

It is important to highlight that this entry cannot present a comprehensive review of existing research on primate communication. Thus, although each section focused on specific aspects of the corresponding modality, such as intentional use of gestures, there is an increasing number of studies on intentional vocalizations, as well as context-specific, referential gestures, or expressive movements of other parts of the face than the mouth. However, this entry aimed at pointing to some of these current gaps of knowledge about primate communication together with the existing biases toward specific modalities, because they might have very serious consequences for theories of language evolution, since "...many of the assumptions that are currently held about how vocalizations, gestures and facial expressions compare may not be true" and as a result, the "...absence of evidence for a certain trait may not necessarily reflect absence of ability" (Liebal et al. 2013, p. 209).

## Primate Diet

Joanna E. Lambert  
Departments of Anthropology and Environmental  
Studies, University of Colorado Boulder,  
Boulder, CO, USA

## Definition

Information related to primate food consumption, nutrition, feeding biology, and digestive strategy

## Introduction

The Order Primates comprises 496 number of species in 16 families, distributed throughout Mexico, Central and South America, Asia, Africa, and Madagascar (Mittermeier et al. 2013). Although the earliest true primates, dating to the late Paleocene – early Eocene epochs – were most abundant in regions of North America and Europe, extant primates are primarily a tropical radiation, found in a diversity of habitat types running the gamut in vegetation types, altitude, latitude, rainfall, and seasonality. Modern primate species exhibit extraordinary diversity in all biological variables, but regardless of dietary specifics of their diet, with a couple of exceptions, all primates are highly flexible feeders, derive the vast majority of their calories from plants, and are indeed one of the modern mammal orders that evolved as primary consumers (Milton 1993).

## Description of Diet: Trophic Feeding Labels

Description of wild primate diet began in earnest in the 1970s (Clutton-Brock 1977) and relied on feeding labels derived from a classic trophic food chain. In this classificatory system, dietary categorization is based on where an organism falls within a system of energy transfer from one trophic level to the next. The ultimate source of energy comes in the form of UV radiation which is fixed into carbohydrate energy by the first trophic level (producers) comprised of plants. Those organisms that consume plants only make up the second level and are labeled primary consumers. Secondary consumers are those organisms in the third trophic level that consume primary consumers and so on. From this system of energy transfer, we gain the terms herbivory (primary consumers), carnivory (secondary and tertiary consumers), and omnivory (herbivory + carnivory). Because many primates augment their plant diet with some percentage of animal foods (primarily invertebrate, but also vertebrate), they are most properly referred to

as omnivores. Nonetheless, among primates, most calories are derived from the producer trophic level, and in many tropical forest habitats, primates can represent a significant percentage – if not majority – of arboreal primary consumer biomass (Janson and Chapman 1999).

From this basic description of diet are an associated set of labels that have been used to describe primate diet in more specific terms related to the form of plant or animal matter consumed, with most species described as being either a frugivore (fruit-eater), folivore (leaf-eater), granivore (seed-eater), gumnivore (gum-eater), insectivore (insect-eater), or faunivore (animal-eater, synonymous with carnivore). These terms linger in the literature and have been the primary means by which to describe primate diet. Moreover, they are often used as a quick index for particular primate taxa. Folivory, for example, is ubiquitous among the Colobinae (leaf-eating monkeys), the genera *Indri* (Indridae) and *Alouatta* (howler monkeys), and *Gorilla beringei beringei* (mountain gorillas). Frugivory is found widely throughout the order but is noted particularly in Atelinae (spider, woolly, and muriqui monkeys), the true lemurs (*Lemur*, *Eulemur*, *Varecia*), and the genus *Pan* (common chimpanzees and bonobos). Seed eating (granivory) is common among Pitheciinae (saki and uakari monkeys) and, to a lesser degree, Colobinae. Gumnivory is observed in the Cheirogalidae (mouse and dwarf lemurs) and Callitrichidae (marmosets and tamarins). Insectivory (a form of carnivory) is seen in particular among the Cheirogalidae, the genus *Saimiri* (squirrel monkeys), and redtail guenons (*Cercopithecus ascanius*). Exclusive faunivory is extremely rare and is found only in the genus *Tarismus* (tarsiers), although some lorises (e.g., *Loris*, *Arctocebus*, *Galagoides*) can be almost 100% in some habitats and in some seasons.

## Description of Diet: Generalist and Specialists

Primate species are also often described in terms of whether they are generalist or specialist

consumers. These terms derive from classic niche theory in which niche width is indicative of whether a species consumes a broad array of food species/parts and thus has a wide dietary niche width or eats a narrow spectrum of food species/parts and thus has a narrow niche dietary space. Overall, primates are generalists, with some taxa particularly so. Extreme dietary generalists also tend to be among the most successful and widespread extant taxa. For example, baboons (*Papio*) and macaques (*Macaca*) are found, respectively, throughout sub-Saharan Africa and regions of Asia and have diet that are marked by extreme eclectic omnivory, with hundreds of species consumed, and high feeding plasticity depending upon food resource availability (Richard et al. 1989; Altmann 1998; Lambert and Rothman 2015).

However, several primate taxa are noteworthy as dietary specialists – it is in these taxa that derived anatomical and behavioral adaptations for procuring and processing food are observed. The Colobinae, for example, are unique among primates in having a modified stomach that facilitates plant fiber (hemicellulose, cellulose, lignin) fermentation and specialized folivory, similar to the digestive strategy of ruminating artiodactyle ungulates. In this system – known as foregut fermentation – the stomach is sacculated into either three or four haustrated chambers that vary in function and pH. The first of these stomach chambers – the forestomach – has a high pH suitable for housing hundreds of bacterial, fungal, and eukaryote symbiont microbe species that ferment dietary plant fiber. The short-chain fatty acids released as a metabolic by-product of this microbial fermentation serve as the primary source of energy for the colobine consumer (Lambert and Fellner 2011). In another example of dietary specialization, the golden bamboo lemur (*Hapalemur aureus*) feeds almost exclusively on grasses, particularly bamboo – some of which are very high in cyanogenic glycosides. In some seasons, *H. aureus* can consume upward of 12 times the lethal dose of cyanide for mammals of their body size (Glander et al. 1989). This strategy is not seen in any other primate taxon, and although the exact mechanism by which

detoxification takes place is unknown, it almost certainly involves specialized microsomal enzyme(s) produced in the endoplasmic reticulum of liver cells (Freeland and Janzen 1974).

## Dietary Flexibility and Nutritionally Explicit Description of Diet

Regardless of which standard trophic label is applied or whether a primate taxon is deemed generalist or specialist, diet is highly variable throughout the course of an animal's lifetime, between individuals and between populations. In some cases, within-species variance in diet can exceed that of interspecific differences (e.g., within and among *Cercopithecus* species; Chapman et al. 2004). Circumscribed terms, such as “frugivore,” “folivore,” etc., fail to capture this plasticity and can obfuscate the underlying reason why a consumer is eating what it is eating and when.

Diet variability is influenced by both *intrinsic* and *extrinsic* factors. *Intrinsic* factors can refer to the inherent features of a plant food (e.g., nutritional, chemical, mechanical attributes of leaves versus insects) or to intrinsic elements of species' particular adaptations and how this varies by age, sex, reproductive, social, and health status. *Extrinsic* factors influence what, when, and how a primate eats and are a function of the current ecological availability of a food and the costs (e.g., competition – a cost of group living) associated with feeding on it as a consequence of that availability; extrinsic challenges to feeding are influenced hugely by habitat and season.

It is important to keep in mind that primates do not eat insects, fruit, and leaves because they are in need of an insect, fruit, or leaf per se – these ecological units are just the packaging for what primates are eating them for: nutrients and energy. Nutrients can be broken down into the energy-yielding macronutrients (carbohydrates, protein, lipids) and micronutrients (vitamins and minerals), which do not provide energy, but instead facilitate the use of the macronutrients and their conversion into energy. Energy is not a nutrient, but an abstraction that references the caloric gain

from converting the macronutrients into their constituent units. In wild primate diet, fruit pulp generally provides simple carbohydrates (sugars, digested autoenzymatically by the consumer), while leaves are the source of more complex structural carbohydrates (fiber) which must be fermented by symbiont microbes. Similarly, saps are high in simple sugars and gums high in structural carbohydrates. Seeds are good sources of protein and also lipids, although they can be high in plant toxins. Protein is provided to the consumer either in the form of insects (more common in smaller – bodied primates because of the constraints of capture rate) or leaves (more common in larger bodied primates because of the constraints of fermenting large amounts of fiber). Insects and other animal prey also provide lipids.

Primate feeding has most recently been described using nutritionally explicit models and not – as has been done most commonly – in terms of the percentage of plant parts or species in the diet. In so-called nutritional geometry models, diet is depicted in multidimensional space representing nutritional targets of protein, carbohydrate, and lipids (Simpson and Raubenheimer 1993). The resulting ratio of macronutrients is a measure of the nutritional decisions an animal makes which, in turn, are indicators of state-dependent nutritional requirements of that animal (Felton et al. 2009). Using this approach, it has been demonstrated that mountain gorillas will overconsume protein in their leafy diet to arrive at a prioritized energy target (an “energy-leveraging” strategy), while spider monkeys (*Ateles chamek*) will overconsume energy to arrive at a protein target (a “protein-leveraging” strategy) (Felton et al. 2009; Rothman et al. 2011).

## Synonyms

[Lemur](#), [Tarsier](#), [New World and Old World Monkey](#), and [ape locomotion](#); [Primate movement](#)

## Definition

Patterns of movement observed in members of the order Primates.

Among tetrapods, the locomotor behavior of primates has been the best studied (see Granatosky 2018 for a review). The reason for this bias is twofold. First, *primate locomotion* tends to be fast and highly acrobatic. As such, it is hard for any observer to ignore such feats. Next, as primates ourselves, we have an inherent fascination in the movements of our closest ancestors.

It has often been asserted that primates display the highest locomotor diversity compared to any other mammalian group (Hunt et al. 1996; Vilensky and Larson 1989). This high degree of locomotor diversity observed in primates has been considered an essential adaptation potentially responsible for the evolutionary success of the

order (Schmitt et al. 2016), and it is this assumption that has led to numerous studies documenting locomotor behaviors across a broad phylogenetic spectrum of primate species. These locomotor profiles have provided essential information about behavioral ecology, functional morphology, paleontology, and, by extension, important data concerning primate locomotor evolution (Fabre et al. 2017; Hunt et al. 1996).

There has been extensive speculation as to what factors of primate biology might have led to the considerable diversification of locomotor modes (Cant 1992; Granatosky 2018; Vilensky and Larson 1989). Perhaps the most cited explanation is the link to a long, and potentially restricted, evolutionary history tied to an arboreal environment in early primates (Cartmill 1992; Schmitt et al. 2016; Schmitt and Lemelin 2002). The arboreal milieu is characterized by considerable variation in substrate diameter, orientation, compliance, and continuity. The complexity of this environment is thought to have put strong selective pressures on the ability of primates to rapidly switch between disparate locomotor behaviors to effectively adjust to substrate variation (Schmitt et al. 2016). In contrast, terrestrial environments are commonly considered less complex, and animals within these environments likely must deal with lower substrate variation. The greater substrate homogeneity observed in terrestrial landscapes is thought to relax the need to switch between different forms of locomotion to successfully traverse the environment (Granatosky 2018).

Another explanation for the greater locomotor diversity in primates comes from inherent features of primate anatomy. In general, primates retain a primitive and generalized post-cranial skeleton with grasping hands and feet and highly mobile limb joints (Granatosky et al. 2016; Larson 1998; Schmitt et al. 2016). Together these features allow most primates greater flexibility in overall range of motion, and therefore capable of proficient locomotion in a number of environmental contexts (Schmitt et al. 2016; Vilensky and Larson 1989). However, there are numerous primate species that have evolved anatomical specializations away from the primitive body plan to better fit a

particular form of locomotion (e.g., vertical-clinging and leaping or suspensory behavior) or environmental context (Fleagle 2013; Hunt et al. 1996; Preuschoft 2002). For these species, it has been suggested that overall locomotor diversity is lower when compared to more anatomically generalized species (Fleagle 2013; Granatosky 2018). Body mass also has been argued to influence the locomotor behaviors of primates. Specifically, smaller species/individuals are considered to use a greater range of locomotor behaviors than larger species/individuals that may be restricted in the locomotor modes they are able to adopt due to their larger body mass (Cant 1992; Fleagle 2013; Granatosky 2018).

Major Locomotor Modes

Although *primate locomotion* can be quite diverse, there are five locomotor modes observed most often among the nonhuman primates (Fig. 1). Quadrupedalism remains the most

common form of *primate locomotion* and is often considered the basal locomotor mode for the order (Hunt et al. 1996). Compared to most mammals, primate quadrupedal walking gaits are differentiated by a suite of at least three features (Granatosky et al. 2016; Schmitt and Lemelin 2002). First, primates tend to utilize diagonal-sequence footfall patterns (i.e., each hindlimb footfall is followed by a contralateral forelimb footfall), whereas most other quadrupedal mammals use primarily lateral-sequence footfall patterns (i.e., each hindlimb footfall is followed by an ipsilateral forelimb footfall; Cartmill et al. 2002; Granatosky et al. 2016, 2019). Second, quadrupedal primates exhibit a relatively more protracted position of the humerus at touchdown (Granatosky et al. 2016), whereas other quadrupedal mammals display relatively retracted humeral positions at forelimb touchdown (Larson et al. 2000). Finally, most quadrupedal primates experience higher peak vertical forces on the hindlimbs relative to the forelimbs, resulting in a relatively lower forelimb to

**Primate Locomotion, Fig. 1** The percentages of locomotor behaviors observed for extant mammals. Adapted from Granatosky (2018)

hindlimb peak vertical force ratio (Granatosky and Schmitt 2019; Schmitt and Lemelin 2002). In contrast, most other quadrupedal mammals are characterized by a relatively higher forelimb to hindlimb vertical peak force ratios (Demes et al. 1994; Schmitt and Lemelin 2002) (Fig. 2).

A specialized form of quadrupedal walking called knuckle-walking is seen exclusively in African apes. During knuckle-walking, the palm and proximal phalanges are elevated above the substrate and the hand can be pronated or partially supinated (Fleagle 2013; Schmitt et al. 2016). Flexion at the intermediate phalangeal joints positions the dorsal aspect of the middle phalanges in contact with the substrate as the main weight-bearing elements. The metacarpal phalangeal joints are held in a neutral position (i.e.,  $180^\circ$ ) or slightly hyperextended. It is thought that African apes adopt knuckle-walking postures to reduce bending loads that their fingers would experience in palmigrade or digitigrade postures (Schmitt et al. 2016; Tuttle 1967).

After quadrupedal walking, leaping represents the second most common form of *primate locomotion*, although leaping is quite rare in animals over a certain body size (e.g., orangutans are unlikely to leap; Cant 1992; Granatosky 2018). There are two basic modes of leaping for primates. Most anthropoids utilize an unspecialized form of leaping in which they launch themselves outward along a horizontal plane and then fall downward. This leaping mode is not associated with any notable anatomical specializations. In contrast, vertical-clinging and leaping is a type of *primate locomotion* in which animals adopt orthograde postures at rest on vertically orientated substrates, and movement is initiated through powerful hindlimb extension resulting in animals leaping from one vertical substrate to another (Demes et al. 1999; Fleagle 2013). Vertical clinging and leaping is common among strepsirrhine primates and is also observed in the tarsiids and callithricids (Fleagle 2013; Gebo 1987).

**Primate Locomotion, Fig. 2** Three locomotor characteristics that distinguish primates from other nonprimate mammals. Primates (right) use (a) diagonal-sequence walking gaits (i.e., footfall of right hindfoot is followed by that of left forefoot). In comparison, most nonprimate mammals (left) use lateral-sequence walking gaits (i.e., footfall of right hindfoot is followed by that of right forefoot). Primates also tend to have (b) protracted humeral positions at forelimb touchdown (i.e., humeral angles

greater than  $90^\circ$  relative to horizontal body axis), in comparison to most nonprimate mammals that have more retracted humeral positions at forelimb touchdown (i.e., humeral angle less than  $90^\circ$  relative to horizontal body axis). Finally, when landing on a substrate, (c) forelimbs of primates experience lower peak vertical substrate reaction forces than do hindlimbs. The reverse is true for most other nonprimate mammals. Figure from Schmitt and Lemelin (2002).

The anatomy of vertical-clinging and leaping primates is characterized by relatively long hindlimbs in comparison to the forelimbs (Gebo 2011; Granatosky et al. 2016). These specialized primate leapers generate tremendous forces during takeoff and landing that are orders of magnitude larger than those experienced during typical primate quadrupedal locomotion (Demes et al. 1999). Most arboreal and terrestrial quadrupeds experience peak hindlimb substrate reaction forces that are ~50–100% of body weight (Fabre et al. 2017; Granatosky and Schmitt 2019). In contrast, medium- to large-bodied primates experience forces ~500–1400% of body weight when leaping (Demes et al. 1999; Gebo 2011). Elongated legs help leaping primates generate these incredible external substrate reaction forces, which in turn increases jump height and distance, with relatively little internal muscle force.

Following leaping, climbing is the next most common locomotor mode observed among primates. Climbing, often on vertical supports, is a critical and fundamental form of locomotion for arboreal animals during foraging, travel, escape, or finding a safe resting place (Cartmill 1985; Granatosky et al. 2019; Hanna et al. 2017). In primates, there are two basic types of climbing. The first involves the animal wrapping itself around the substrate. This is observed most among the clawed callitrichid primates and in situations when the diameter of the support is substantially larger than the diameter of the body. In these situations, asymmetrical gaits are most common (Cartmill 1985; Preuschoft 2002).

The second form of climbing is observed most on smaller substrates and involves symmetrical walking gaits [see Granatosky et al. 2019 for a review]. However, unlike quadrupedal walking (see above), lateral sequence gaits are most common (Granatosky et al. 2019). During symmetrical gait climbing, stability and security are paramount. Accordingly, animals usually move more slowly, with longer intervals of grasping the support than what is observed during arboreal quadrupedal walking (Granatosky et al. 2019). As

with arboreal quadrupedal walking, the hindlimb serves as the primary weight support and propulsive limb during climbing (Hanna et al. 2017). This form of climbing is observed across almost all primate species, but has received considerable attention recently in the great apes.

Suspensory positional behaviors are commonly discussed in concert with the hominoids, atelines, and to some extent the Asian colobines, but it should be noted that all primates can, and do, engage in suspensory locomotion, although some groups emphasize these behaviors more effectively, or for longer periods of time (Granatosky and Schmitt 2019; Stern 1975). For most, images of suspensory locomotion are centered on what is commonly referred to as arm-swinging, a form of forward progression in which the animal hangs below the support and the forelimbs bear most of the weight. Arm-swinging may be associated with prehensile tail use in the New World atelines (Byron et al. 2017; Fleagle 2013). The morphology of arm-swinging species has been well studied and is often interpreted as a functional suite of characteristics thought to allow for efficient pendular movement (Bertram 2004; Byron et al. 2017). The fluid, swinging motion observed when brachiators move beneath branches naturally brings to mind the oscillations of a pendulum and the repeated interchange of potential and kinetic energy (Bertram 2004; Byron et al. 2017). It is tempting, then, to assume that arm-swinging primates use natural pendular motions to reduce the muscular investment necessary to travel. Some studies have demonstrated that, under certain conditions, arm-swinging primates do match the expectations of a simple pendulum, but this appears to be the case only for very slow speeds and continuous-contact locomotion. Simple pendular locomotion is restrictive, and to optimize energetic efficiency, animals must limit themselves to a narrow range of stride distance and speed. In most scenarios, the complex three-dimensional arboreal environment that arm-swinging primates live in makes simple pendular locomotion impossible. In these situations, travel pathway adjustments, rather than efficiency,

appears to be the primary concern (Byron et al. 2017; Chang et al. 2000; Fleagle 2013).

It is important to note that many primates utilize below branch quadrupedal locomotion, which is a form of suspensory locomotion in which both the forelimbs and hindlimbs are used in some combination, the torso is pronograde, and the limbs are loaded in tension (Granatosky and Schmitt 2019; Stern 1975). This behavior is like the movement of a sloth, and is common in the lorises, orangutans, and many platyrrhine monkeys. While movements of the limbs are largely similar to what's observed during arboreal quadrupedal locomotion (see above), the forelimb becomes the dominant weight bearing limb. This finding has led some to suggest that below branch quadrupedal locomotion may be a mechanical intermediate transition to arm-swinging (Byron et al. 2017; Granatosky and Schmitt 2019).

Finally, almost all primates demonstrate some bipedal tendencies (Granatosky 2018; Hunt et al. 1996). This is most notable in humans, but also common in great apes, capuchin monkeys, and sifakas. Bipedal walking in humans is often referred to as "striding", which is largely attributable to the smooth means of traveling during which the energy output of the body is reduced to a physiological minimum (Preuschoft 2004; Sockol et al. 2007; Yamazaki et al. 1996). Just as arm-swinging is often equated with a simple pendulum, bipedalism is equated with the interchange of potential and kinetic energy of an inverted pendulum. It is a complex activity involving the joints and muscles of the whole body (Yamazaki et al. 1996), and it is likely that the evolution of the human gait took place gradually over a period of ten million years (Fleagle 2013). The pattern of locomotion of human ancestors immediately preceding the acquisition of bipedalism has long been a matter of controversy. Based on the close phylogenetic position with chimpanzees and gorillas, there is potential that the earliest human ancestors used knuckle-walking (Richmond et al. 2001). However, this has been fiercely debated and other locomotor modes like the slow suspensory progression of the orangutan may be more likely (Stern 1975). Most likely, the earliest hominins

had a wide locomotor diversity, like the orangutans, and found bipedalism to be an acceptable means to traverse a landscape with more open savannahs and less tree cover (Fleagle 2013; Stern 1975).

## Conclusion

This chapter introduces the diversity of primate locomotor behaviors. There has been extensive speculation as to what factors of primate biology might have led to the considerable diversification of locomotor modes. The most cited explanation is the link to a long, and potentially restricted, evolutionary history tied to an arboreal environment and/or maintaining a generalized postcranial anatomy. Compared to other mammals, primates tend to utilize diagonal-sequence foot-fall patterns, exhibit a relatively more protracted position of the humerus at touchdown and experience higher peak vertical forces on the hindlimbs relative to the forelimbs. This odd combination of gait characteristics is likely linked to maintaining stability in an arboreal environment, and may have allowed primates to evolve different locomotor behaviors, such as vertical climbing or bipedalism. Primates are also the only mammalian group to have developed arm-swinging locomotion. There is considerable ongoing research on *primate locomotion* and open questions remain about the origins of primate quadrupedal locomotion, arm-swinging, and bipedalism.

## Definition

A primate orphan is an immature individual who has lost his or her mother as an infant or a juvenile.

## Introduction

In infancy, all primates require a caregiver who meets their physical needs, such as food and protection (among many others), and their affective, cognitive, and social needs (in some species, this requirement extends until the primate is a juvenile). The caregiver is essential for primate infant survival and social and cognitive development. For that reason, infants are greatly affected if they lose their caregivers; the effects of becoming an orphan range from being unable to survive to behavioral and physiological consequences that last through adulthood. Here the relevant aspects of the study of primate orphans are reviewed.

## Chances of Survival

Primates have a long period of dependency on their mothers. For example, infant chimpanzees require considerable amounts of care during long periods of dependency. Chimpanzee mothers stop carrying and nursing their offspring when the offspring are around 4/5 years old, but for several years thereafter, mother and offspring maintain close spatial proximity. Mothers also defend their offspring against aggression and wait for them during group travel. Young chimpanzees travel almost constantly with their mothers and her other immature offspring (frequently their siblings) until mid-adolescence (<12 years). Orangutans in the wild are dependent on their mothers for food and travel until they are 2.5 years old, and until the age of 7 years, they spend a large amount of time with their mothers, although they are capable of feeding and traveling independently. Gorillas also exhibit this kind of maternal dependency; however, the western lowland gorilla (*G. beringei*) shows greater infant dependence than the mountain gorilla (*G. gorilla*). It is also possible to find this same

kind of dependency in infant and juvenile monkeys; the dependency on mothers (as measured by rates of travel, contact among others) varies, depending on the parenting style of the mother and on environmental conditions. Young primates who lose their mothers are extremely vulnerable; orphaned infants are left without their main source of protection, transportation, food, and comfort, and this loss will likely result in an infant's death. If individuals lose their mothers later in life, despite being capable of finding their own food and traveling independently, they still suffer an enormous loss; they lose their main companion for travel, their main source of comfort, and the most important source for help when navigating the constantly changing social environment of their communities.

Despite the common recognition of the impact of the loss of a mother on a primate orphan, there are conflicting reports of the ability of infants and juveniles to survive after a mother's death (see, e.g., the different rates of survival of orphan chimpanzees reported by Goodall 1986, and Boesch and Boesch-Achermann 2000). Several researchers have attempted to determine the factors that affect an infant's ability to survive after losing their mother. Most researchers agree that the survival of orphans depends upon the timing of a mother's death and the presence of other individuals who might care for the orphaned infant.

Most authors agree that the survival of orphaned infants depends upon whether they lose their mothers after they have been weaned and whether they find another caregiver who can take care of their basic needs. However, there is no agreement regarding the exact age, after being weaned, at which infants are capable of survival. For example, it has been argued that, in chimpanzees, the survival of an orphan before weaning is impossible and that the care provided by siblings usually ensures that orphan's survival, as long as the orphan is at least 4.5 years old. This is because chimpanzees have a very long period of dependence on mother's milk; they are weaned at 4.5–5 years. Moreover, most direct maternal investments, such as maternal transportation of infants and sharing of night shelters (beds or nests), end

when the infant is weaned. Consequently, it has been argued that offspring younger than 4.5–5 years old cannot survive if the mother dies, and it is assumed that a mother's death is no longer critical to the survival of weaned offspring. However, long-term demographic data for a wild chimpanzee population in the Mahale Mountains, Tanzania, show that orphaned chimpanzee sons die younger than expected if they lose their mothers even after weaning (Nakamura et al. 2014). In bonobos (*Pan paniscus*), there have been recorded cases of infants who survived even though they were orphaned before being weaned (De Lathouwers and Van Elsacker 2007).

## Adoption

Despite the disagreement on the age at which independent survival is assured, most authors agree that, for an infant to survive, it is necessary that the infant find another individual who provides care similar to a mother's care. To ensure their survival, infants must be adopted by another individual who provides nursing and/or food-provisioning, carrying, active vigilance during group travel, defense, grooming, and comforting behavior. Boesch et al. (2010) define *adoption* as the provision of species-specific *allomaternal* care (e.g., nurturing behavior normally provided by the biological mother to her dependent offspring, such as carrying, sharing food, defending, or grooming) to an orphan by an adult or mature individual (older than 12 years old) for at least a 2-month period. Boesch also claims that, to be considered an adoption, the adult who adopts the infant must frequently associate with the orphan and exhibit behaviors such as waiting during travel, providing protection in conflicts, and sharing food with the orphan. However, it is important to notice that others have argued that this definition of adoption should be expanded to include reported cases of the adoption of infants by younger individuals.

It is interesting to notice that despite the basic similarities between the behavior of biological mothers and adoptive caretakers (e.g., nursing and/or food-provisioning, carrying, active

vigilance during group travel, defense, grooming, and comforting behavior), researchers have reported differences between the behavior of these two kinds of caregivers. For example, it is common that in species whose infants are typically carried by mothers, biological mothers in monkeys and apes continue traveling and do not wait for their infants. However, both maternal siblings and maternally unrelated adopters are unwilling to leave lagging adoptees behind; instead, they wait for and carry them (see, e.g., in baboons, Hamilton et al. 1982).

### Variables in the Adoption Process

The adoption of orphans has been documented in monkeys and apes (see, e.g., in savanna baboons, Altmann 1980; chimpanzees, Goodall 1986; bonobos, Surbeck and Hohmann 2017; red howler monkeys, Agoramoorthy and Rudran 1992; black and white colobus monkeys, Dunham and Opere 2016; titi monkeys, Cäsar and Young 2008). Researchers have determined the relevant factors that contribute to a successful adoption process.

First, in different captive situations, it has been observed that the experience/age of the adoptive mother is a contributing factor in the successful adoption of an infant. For example, in orangutans (*Pongo pygmaeus*) in captivity, successful introductions of infant orangutans to surrogate mothers have been described (Maple 1980; Sodaro 2007); in most cases, the previous mothering experience of the adult females who adopted the infants contributed to the success of the surrogacy.

Second, variations have been found with regard to the identity of the individual adopting the orphan (e.g., kin, non-kin, sibling, grandmother). Traditionally, it has been argued that female siblings are responsible for most successful adoptions; however, in recent years, it has been found that individuals who are not female siblings can also successfully adopt orphans. In chimpanzees, when mothers die, immature orphans are often adopted by a maternal sibling if they have one. However, the same researchers who observed adoptions by maternal siblings in chimpanzees

also documented several cases of adoption in chimpanzees by both maternal relatives and non-relatives, by siblings, by males or nulliparous females, and even one rare case of adoption, by a grandmother without the death of the biological mother (Wroblewski 2008); all of these different types of adoptive caretakers exhibit remarkable care of the orphans. Hobaiter et al. (2014) reviewed data from four different sites, including their own (i.e., Gombe, Mahale, Tāi, and Sonso), and found that, across all four sites, adopters can be classified into the following groups: immature maternal sibling (<12 years) ( $n = 10$ ); mature maternal sibling (12 + years) ( $n = 4$ ); other kin ( $n = 2$ ); and non-kin ( $n = 20$ ). When considering the variation of the identity of the adopters, Hobaiter and colleagues hypothesize that the social bond, rather than biological relatedness, is the main variable that explains the identity of the adopter of orphaned chimpanzees. However, in most cases, maternal siblings are the ones who have a closer social bond to the orphaned infant. Upon reviewing data from all sites, the authors did not find that the adopter's age nor that the social relationship between the orphan and the adopter predicted the survival of the infant. Only the orphan's age predicted their survival rate: 100% of orphans aged 6 years or older and 95% aged 4 years or older survived. Meanwhile only 42% of orphans under the age of 4 years and 20% of orphans (one case,  $n = 5$ ) under the age of 1 year survived.

Several reports of monkeys have shown that juvenile and infant orphans were fostered by their siblings and non-related adult males (see, e.g., in Japanese macaques (*Macaca fuscata*), Hasegawa and Hiraiwa 1980). Several researchers also have argued that caregiving by grandmothers is rare. However, some exceptions have been recorded (see, e.g., in Japanese macaques, Nozaki 2009).

The adoption of primates by siblings has been explained as a way in which older siblings of individuals gain inclusive fitness benefits from assisting relatives (Hamilton 1964). However, it is not clear why non-siblings adopt orphans. Some have argued that different forms of adoption (i.e., males, females, siblings, non-siblings) can be examined through differences of ecological

and social effects such as seasonality (e.g., birth season, mating season, number of orphans, demographics). Boesch et al. (2010) suggest that adoption by wild chimpanzees should be interpreted as a potential example of altruistic behavior, mainly because of the significant costs that adoption has for the individual who adopts an orphan.

Finally, a third variable in the adoption process is differences among communities; in some cases, it is hypothesized that ecological factors account for these differences. For example, in East African chimpanzee communities (i.e., Gombe and Mahale), cases of older maternal siblings and nulliparous and infertile females adopting orphan chimpanzees have been reported. Most of the reported cases of adoption involve kin-adopters, even if the adopters are still immature and even if mature non-kin adopters are available. Meanwhile in the West African communities (i.e., T   Forest, Ivory Coast) most of the adoptions reported have been done by unrelated (non-kin) mature individuals such as adult males (one father) and parous females who have been allies of the deceased mother with no known kin relationship. However, it is important to clarify that this type of non-kin adoption occurs only if no maternal siblings are available and often only after significant time periods (e.g., weeks or even months; see Hobaiter et al. 2014, for an overview).

It has been argued that ecological pressures, such as the presence of predators and mortality rates, have an influence on the rates of adoption among these different communities (Boesch et al. 2010).

### Effects of Losing Mother

As stated, losing their mother is devastating for primate infants, even when they are subsequently adopted; the lack of a mother can have multiple behavioral and neurophysiological effects throughout the orphan's life. In several species, orphans can experience decrements in growth, reproduction, and longevity and suffer from negative impacts on health, social status, and emotional development such as anxious

behavior and effects on their ability to engage in successful social interactions, with declines in play and other social responses and increases in abnormal behavior, such as lethargy, rocking, and hair plucking (see, e.g., in baboons, Tung et al. 2016; chimpanzees, Nakamura et al. 2014; Walker et al. 2018; bonobos, Clay and de Waal 2013). These effects are much stronger in chimpanzees who become orphans as the result of bushmeat practices and the pet trade (see, e.g., Lopresti-Goodman et al. 2013).

Despite recognizing the effect that losing their mother has for chimpanzees, there is no agreement about what is the minimal age (i.e., time spent with mother) that buffers chimpanzees from serious negative effects. Bloomsmith et al. (2005) performed a review of the existing data on chimpanzees in captivity and concluded that chimpanzees who were separated from their mothers in laboratory settings but lived with their mothers for at least 1 year before the separation exhibited little rocking behavior and four times as much maternal competence as adults (when compared to individuals separated from their mothers before the age of 1 year). They found no behavioral differences in subadulthood between laboratory infants separated from their mothers after age 2 and peer-reared and mother-reared infants. The authors concluded that if chimpanzees spend 2 years with their mothers before separation, they will not exhibit abnormal behaviors. However, these results are in opposition to Botero et al. (2013) who observed the behavior of orphaned chimpanzees who lived in their natal communities when their mother died; they reported anxiety-related behaviors and diminished rates of play in chimpanzees orphaned much later than 2 years of age.

Other researchers have described behaviors of orphaned juveniles changes that do not seem detrimental to the individual such as imitation and other cognitive abilities (see, e.g., in free-ranging rehabilitant orangutans (*Pongo pygmaeus*), Russon and Galdikas 1995). Others have described outcome behaviors that do not seem either detrimental or positive to the individual such as higher levels of social attention (i.e., directing visual attention at conspecifics) and

increases in climbing and object manipulation (see, e.g., in vervet monkey (*Chlorocebus pygerythrus*), Grampp et al. 2019)

Most of the research regarding the effect of the absence of the mother for chimpanzees and infant and juvenile monkeys has been conducted with populations in captivity. Several authors have reported negative behavioral effects for chimpanzees (e.g., anxiety, rocking behavior, lower levels of play, disorganized attachment styles) who had to be separated from their mothers and were reared under limited human interaction or in peer groups. Research in monkeys in captivity has shown that prolonged or repeated maternal separations are associated with lifelong dysregulation of physiological systems and an increased risk of pathological emotional development, including hormonal changes and enlargement in stress-sensitive brain regions, among other effects (see, e.g., in rhesus monkeys (*Macaca mulatta*), Conti et al. 2012).

It is not clear whether these effects are also present in orphaned monkeys in captivity. In opposition to the previous studies, several studies found negligible differences in infancy and post-infancy behaviors (i.e., maternal–infant interactions and neuroendocrine and behavioral responses to separations) between adopted and non-adopted rhesus monkeys in infancy and post-infancy behaviors (see, e.g., in rhesus monkeys, Champoux et al. 1995). Nor it is clear that these effects are present in wild populations, some researchers found no differences in the behavior of orphans (see, e.g., free-ranging male rhesus monkeys, Drickamer and Vessey 1973). Moreover, some research shows positive outcomes of orphans in monkeys (see, e.g., rhesus monkeys, Itoigawa 2001).

Researchers have also focused on the effects of losing a mother on the social relationships of the individual. These effects include an increase in the amount of time they associated, maintained spatial proximity, groomed, reassured, and consoled their siblings (see, e.g., in chimpanzees, Reddy and Mitani 2019). Another kind of effect on the social relationships for orphan chimpanzees is differences in the behavior of foster mothers and group members toward adopted infants. Foster mothers initially tended to be

more possessive and restrictive of their foster infants (e.g., foster mothers take longer before they allow infants to sit at a distance from them and retrieved them faster). Non-related members of the troop approached and sat in proximity more frequently, engaged in contact, touched, groomed, and lipsmacked the foster infants more often than they did with control infants, although this depends on the social ranking of the foster mother (see, e.g., in rhesus monkeys, Holman and Goy 1988)

## Sanctuaries

One final aspect that is important to consider when examining orphaned primates is the outcome for orphaned primates under the care of sanctuaries (see, e.g., gorillas, King et al. 2005; bonobos and chimpanzees, Wobber and Hare 2011; orangutans, Robins et al. 2013). Most wild sanctuaries are different from zoos and other captive environments because apes have access to primary tropical forests every day. Thus, in this dimension, the sanctuary environments may be better able than other captive facilities to meet the “top 10” requirements for the care of apes in captivity based on the daily choices that are available to them. Moreover, as stated earlier, given the violence and neglect that most of these infants endure before coming to the sanctuaries, the effects of losing their mothers are often more severe than the effects of losing a mother for an infant in other kinds of captivity.

Similar to the studies reviewed earlier, the conditions under which the chimpanzees in these sanctuaries are reared by foster mothers have an effect on their behavior later in life. For example, in a recent and novel study, Ortín et al. (2019) evaluated the effects of bushmeat trade outcomes on the personality development of African sanctuary chimpanzees. Mother-reared chimpanzees were rated as lower in restraint than hand-reared chimpanzees. They were also rated as less dominant than hand-reared chimpanzees.

Overall, despite all these difficulties, most orphan chimpanzees from sanctuaries are capable of successfully adapting to life in the wild after a

rehabilitation period in the sanctuaries. After their release, most of them are able to survive; some of the females gave birth to healthy offspring and successfully immigrated into a wild chimpanzee community (see, e.g., Humle et al. 2011). It is important to notice that despite the detrimental effects of being an orphan, for chimpanzees, under the special socio-ecological circumstances provided by some sanctuaries, the release of wild-born adult chimpanzees of both sexes is a viable strategy to remedy the damage caused by the bushmeat and pet industries.

## Conclusion

Young primates who lose their mothers are extremely vulnerable; orphaned infants are left without their main source of protection, transportation, food, and comfort. To ensure their survival, another individual must adopt the orphan. The foster caretaker will provide the infant a similar kind of care as their biological mothers; they will provide nursing and/or food-provisioning, carrying, active vigilance during group travel, defense, grooming, and comforting behavior. However, future studies are necessary to fully understand the complexity and variation of the adoption process among different communities and environmental conditions and the effect that losing their mother and being adopted has for an orphan primate.

## Primate Perspectives on the Evolution of Human Behavior

Glenn E. King

Department of History and Anthropology,  
Monmouth University, West Long Branch,  
NJ, USA

### Synonyms

[Primate analogies](#); [Primate models](#); [Primate-human homologies](#)

### Definition

The use of primate behavior studies to reconstruct the evolution of behavior in human ancestors and hypothesize about the persistence of primate behavior components in living humans.

### Introduction

Nonhuman primates (often called simply *primates* for convenience) are the closest living relatives of humans. The main groups are apes, monkeys, tarsiers, lemurs, and lorises. For the sake of space and relative simplicity, the examples in this article are limited to monkeys and apes. The term *hominin* encompasses all members and branches of the evolutionary lineage that separated from other primates and produced the human species (Andrews 2020). Primate behavior has been the basis for many inferences about hominin evolution, especially its earliest stages (King 2016; van Schaik 2016). This information can elaborate on and fill gaps in the archeological record. It can also suggest the presence and form of behaviors that left no direct evidence. Though based on extensive learning, primate behavior also displays innate influences (i.e., relatively specific genetic foundations). The same kind of behavioral complexity must have been true of early hominins, and some of the innate components are probably conserved in living humans.

Thus, comparison with other primates can suggest the existence of such innate components and illuminate their interaction with learning in the behavior of early hominins and living humans.

## Hominin Evolution

Our closest living relatives are chimpanzees and bonobos; both species are assigned to the genus *Pan*. The species ancestral to *Pan* and *Homo* is often called the last common ancestor or LCA (i.e., the last ancestor shared by humans with any other primates). It probably existed between 9 and 6 million years ago (mya). From about 4 mya, hominin species proliferated in a geographic arc from Chad through East Africa to South Africa. These *early hominins* (as the term is used here) have been assigned to several genera, including *Ardipithecus* and *Australopithecus*. Earliest *Homo* (e.g., *H. habilis*) can be included in this category. *Homo* emerged about 2.8 mya with characteristics that can be viewed as continuing trends visible in *Australopithecus*, such as slightly larger body size and a slightly larger brain (Kimbel and Villmoare 2016). The appearance of *Homo erectus* (using the term in its broadest sense) marked the turning point toward human adaptation with a major increase in brain size, nearly modern skeleton, lengthened life history stages, and skilled toolmaking; however, primate comparisons have been applied even at this stage (Swedell and Plummer 2019).

Early hominins combined apelike physical traits, such as long arms, with humanlike characteristics, such as habitual bipedalism (Andrews 2020). Probably most individuals weighed between 30 and 50 kilograms. The degree of sexual dimorphism is disputed, but males in some populations may have been almost twice the size of females. Most early hominins lived in “mosaic environments” that included deciduous tropical woodlands and various more open areas, as well as a substantial body of water (lake, river, or floodplain) (Andrews 2020). The diversity of early hominin environments also included geographic variation, fluctuations across time, and a general drying trend.

Explanations for early hominin adaptations can be sorted into three major categories (Maslin et al. 2015). *Savanna/aridification* hypotheses emphasize the effects of hotter and drier habitats, varying from woodlands to treeless grasslands. *Fluctuating environment* hypotheses focus on the ability to adjust to continuous or recurring changes in environmental conditions. *Social* hypotheses emphasize competition within societies, including status negotiation and sexual selection. Living primates are relevant to all three categories because (1) various living primates have adapted to diverse habitats, from woodlands to savannas; (2) long-term studies have demonstrated primate responses to environmental fluctuation; and (3) primate societies are complex and entail both social and sexual competition.

## Primate Models

The term *model* is usually applied to an aggregation of primate data that is organized to generate hypotheses about hominin behavior (Moore 1996). Definitions vary greatly, and a model can be used in a comprehensive way or as a source of inferences about particular traits.

Basic descriptions and critiques were collected by de Waal (2001) and Kinzey (1987). Primate models have been distinguished from one another in various ways, but the methods and results often overlap (King 2016).

**Referential models** use a real phenomenon to illuminate others that are more difficult to study. In this case, the first phenomenon is one or more species of living primates, and the second is human ancestors. Referential models can show possible behaviors, suggest hypotheses, and provide detailed scenarios as a basis for testable predictions (Moore 1996). These models can suggest both general patterns (e.g., type of diet) and details (e.g., consumption of honey). Referential models use several different premises:

**Phylogenetic models** are based on evolutionary relationships among taxa and postulate that related taxa share some kind of genetic foundation for similar behavioral patterns. These may be homologies derived directly from a common

ancestor or parallel developments based on the common biological heritage. *Pan* referential models are predominant in phylogenetic reconstructions of the LCA and early hominins. Where there are behavioral divergences, *Pan* usually provides a more likely model than *Homo* due to similarities to the probable LCA such as limb proportions and brain size. Where the *Pan* species (chimpanzees and bonobos) differ from one another, the choice of a model is debatable, hence, for instance, a long-running controversy about early hominin aggressiveness. In some cases, the *Pan* species and humans may all differ from the LCA.

A solution to such problems is to expand the comparative sample. Gorillas and/or orangutans may be added to form broader ape models. However, their value for the purpose is limited because there are just three ape genera and there are extreme behavioral differences among them. Broader models can be generated by adding gibbons, Old World monkeys, New World monkeys, and prosimians or using the primates as a whole. These larger samples can provide broadly documented evolutionary similarities but at the cost of fewer relevant traits and less detail.

**Functional models** are based on similarity of effect, emphasizing convergence rather than phylogeny. They can address questions about need (adaptations required by particular conditions) and capability (ability of subjects to perform a postulated behavior). Also based on convergence, *attribute models* (also called *trait models*) start with a particular hominin characteristic and seek an analogous trait in extant primates (e.g., transport of toolmaking materials).

The chimpanzee species (*Pan troglodytes*) is of special significance. The genus *Pan*, as noted, shares the LCA with the hominin lineage. The chimpanzee species also occupies a wide range of environments much like those of early hominins. Chimpanzees can provide trait models for selected features (e.g., tool use) or comprehensive models for a total way of life in woodland or savanna (Muller et al. 2017). Examples include varied tool-using and toolmaking practices distributed across groups and populations in patterns that many scientists characterize as cultural

traditions. Baboons (genus *Papio*) also receive special attention. Unlike most other monkeys, they are large-bodied, largely terrestrial primates that have adapted to a wide variety of environments, including deserts and mountains (Fischer and Zinner 2020). Traits relevant to early hominins include male-female associations and multilevel societies. Chimpanzees and baboons both contribute to discussions of predator defense, social intelligence, and prelinguistic patterns in early hominins.

**Conceptual models** draw on general principles from fields such as behavioral ecology and evolutionary psychology to specify relationships pertinent to a particular situation, such as early hominin environments (De Waal 2001; Kinzey 1987). A comparable mathematical approach used regression equations to produce correlations (e.g., group size with body mass) into which a hominin species can be interpolated. This works only if one variable is already known for the fossil species. *Systems models* avoid this problem by using more complex equations to construct functional models of behavioral ecology. Mathematical models can be powerful, but they require more data than others and apply only to traits that occur in many species. The conceptual and referential approaches overlap; some conceptual analyses have produced sets of traits similar to those of particular living species. Referential models continue to be most prominent in linking hominins with living primates.

**Criticism of Primate Models.** Criticisms of primate models for the LCA and early hominins can be sorted into two major categories: doubts about the relevance of the primates themselves and doubts about the relevance of their environments to prehistoric conditions. Many questions are being resolved as we learn more about primates (e.g., complexity of social life and use of stone tools) and the characteristics of early hominins (e.g., sexual dimorphism and retention of arboreal capabilities). Much the same can be said about environment, as primate studies and paleoecology have demonstrated the ubiquity of mosaic habitats, including dry and open areas. The faunas of prehistoric habitats were different from those of today, but there are also crucial

similarities such as feline predators and small mammals to be hunted.

## Primate Perspectives on Ecology

**Food Preferences.** The inertia hypothesis proposed that humans overindulge in the preferred foods of our ancestors when opportunity allows, resulting in numerous diseases and debilitating conditions (Hamilton 1987). In the evolutionary past, it was adaptive to maximize consumption when fluctuating resources were available. The motivational systems changed little, while access increased for some humans in recent times, resulting in consumption of unhealthy quantities. The hypothesis was formulated for meat and sweets, but it also applies to alcohol (Dudley 2014).

Primate evidence, beginning with a broad phylogenetic perspective, argues for the existence of such motivational systems. Most primates consume insects (as do many human populations), and many monkeys and apes eat vertebrates (Watts 2020). In addition to land animals, some primates exploit fish and other aquatics, which would have been available to early hominins living near substantial bodies of water. Three referential species – chimpanzees, bonobos, and baboons – kill mammals for food. Though meat is a small percentage of the overall chimpanzee diet, cost/benefit analysis of skewed distributions demonstrates significant nutritional value for some individuals. Behavior in both *Pan* species (hunting, begging, and appropriating) indicates strong motivation to consume meat. Some chimpanzees seem to hunt cooperatively, which might be relevant to the appearance of some of the larger prey animals in the archeological record.

Human attraction to sweet taste is probably derived from fruit-eating ancestors. Apes emphasize ripe fruit consumption wherever the environment permits. Chimpanzees endure hard work and pain to obtain honey, which is dense in nutrients. Attraction to fruit has an extra dimension in the form of ethanol, which results naturally from fermentation of fruit sugars. The scent of ethanol may attract primates to sites of ripe fruit and

may also act as a feeding stimulant (Dudley 2014). Genetic analysis indicates that an enzyme for metabolizing ethanol originated in African apes about 10 mya, when some probably started foraging on woodland floors where fallen fruits contained higher quantities of ethanol. Some wild chimpanzees engage in long-term and recurrent ingestion of ethanol from palm trees, often in large quantities. In some locations, monkeys steal alcoholic drinks from tourists.

**Ingestion of Nonfoods.** Early hominins probably ingested nonfoods that had health benefits. Geophagy – the intentional consumption of earthen materials, including soil, chalk, and clay – is widespread among humans and other primates on all continents inhabited by both (Pebsworth et al. 2019). A common feature is the presence of clay minerals such as kaolinite, which humans have long used in antidiarrheal and topical medications. Primate geophagy is also adaptive in providing essential dietary elements, as well as protection against toxins, pathogens, parasites, and gut irritants.

Non-nutritional plant matter also provides health benefits. Sick chimpanzees get chemical relief from intestinal parasites by chewing bitter pith, and several ape species swallow whole leaves that cause the expulsion of parasites. Japanese macaques display some similar patterns. Remains of plants in archeological assemblages include species that are both edible and medicinal along with some that have no value other than medicinal properties. The proportion of medicinal plants at surveyed sites was well above the natural average, so the inclination to self-medication may have been conserved throughout hominin evolution.

**Predator Responses.** Primates are prey to other animals. Snakes eat primates, and poisonous snakes may also strike defensively (Isbell 2009). Primate responses suggest innate visual mechanisms: recognition that distinguishes snakes from other animals and from the immediate environment, followed by close attention. Other behavioral responses vary: flight, avoidance, aggression, and curiosity. Young primates seem to learn agonistic responses from adults by watching them freeze, flee, utter alarm calls, or

mob snakes. Some variation in primate responses may be related to size: constrictors are frequent predators, and many poisonous snakes in primate habitats are large.

Human responses to snakes are comparable to those of other primates and suggest an evolutionary basis beyond the LCA (King 2016). Humans orient strongly to snakes in various experiments, and ontogeny suggests an evolved basis: infants and children orient more rapidly and more often to snakes than to other stimuli. Experiments indicate that the fear component is learned in humans, as in other primates. Cross-cultural evidence shows that humans consistently pay more attention to snakes than to most other animals, while symbolic characterization of snakes varies from dangerous to benevolent.

Early hominins also faced mammalian predators similar to those of recent times, such as big cats and hyenas. Having retained ancestral climbing abilities, they must have escaped into trees when possible and probably slept in trees. However, if trees were not available, they had to flee or fight. Evidence from baboons and chimpanzees, large primates living in large groups, indicates that fighting was a possibility.

## Primate Perspectives on Technology

**Weapons.** One of the most important roles of primate functional models is to demonstrate behaviors possible to small-brained early ancestors. Decreasing size of the canine teeth, combined with increasing exposure to open habitats, suggests a need for nonanatomical weapons to defend against predators. Wild chimpanzees suggest two possibilities. One case is the spontaneous use of sharpened sticks to kill bush babies for food (Pruetz et al. 2015), which indicates that thrusting spears for defense could have been an early invention. Club use is suggested by chimpanzee use of sticks against a mechanical leopard (in an experiment), a real leopard, and a drone that was knocked out of the air (van Hooff and Lukkenaar 2015). Bipedal hominins could have carried spears or clubs as they traveled.

Captive apes throw various objects, sometimes learning great accuracy, and some researchers think that throwing affected the evolution of hominin anatomy and neurology (Lombardo and Deaner 2018). Stone throwing would have been useful to early hominins (against competitors as well as predators) if they accumulated a sufficient quantity at resting or feeding locations (a parallel argument has been made for caching of butchering tools by early hominins). One zoo chimpanzee was said to plan for future weapon use when, on numerous occasions, he collected and cached rocks that he threw at human visitors later in the same day (Osvath 2009). Shettleworth (2010) doubted that the behavior represented foresight. This illustrates the need to distinguish between different types of analogy. Regardless of the underlying cognitive process, the chimpanzee's behavioral sequences (empirically verified on multiple occasions) provide a functional analogy for possible hominin behavior.

**Extraction.** The idea that early hominins might have accumulated stones for throwing is consistent with data on numerous wild primates transporting appropriate tools to subsistence sites. All great ape genera use tools for various purposes in the wild and in captivity. According to phylogenetic models, this makes some tool use by the LCA probable. Several monkey species also use tools, which suggests potential for convergence (Carvalho and Beardmore-Herd 2019). Chimpanzees are especially versatile in making and using tools of perishable materials, such as the termite probes famously reported by Jane Goodall. Such tools would leave no traces in the archeological record but could have been crucial for the survival of the LCA and early hominins. Chimpanzees use sticks to probe nests for various insects and honey, kill bush babies in tree holes for food, excavate plant storage organs from the ground, and get water during dry seasons by digging holes in sandy riverbeds. Digging near standing pools, they obtain water filtered free of algae and detritus – perhaps the conscious purpose of the behavior. Whether reasoning by homology or analogy, these and other cases of primate tool using suggest possible if not probable early hominin behaviors based on mental capability derived from the LCA.

**Stone.** Though long considered characteristic of *Homo*, stone tools were used earlier, perhaps before 3 mya. Primate behavior suggests antecedent developments (Carvalho and Beardmore-Herd 2019). Chimpanzees smash hard-shelled fruits against tree trunks and thick branches. On the ground, they use stone hammers to crack fruits and nuts placed on tree roots or stones as anvils. After use by the apes, these tools resemble remains found at early hominin sites. Capuchin monkeys also crack nuts with stones on stone anvils. Chimpanzees crack tortoise shells, and long-tailed macaques break open shellfish with stones, which suggests how early hominins obtained food from the bodies of water in their habitats.

Eventually, the most important hominin tools were made from stone flakes. The potential for this invention is demonstrated by the residue of stone-on-stone percussion by capuchin monkeys: sharp-edged flakes and cores that resemble early hominin lithics. The capuchin data demonstrate that humanlike cognition, coordination, and manual dexterity are not prerequisites for stone flake production and that attributing intentionality based solely on findings in the archaeological record is questionable for the earliest cases (Carvalho and Beardmore-Herd 2019). In captivity, a few bonobos and an orangutan have learned to use flake tools for cutting, but no such behavior has been seen in wild primates.

**Sequential tool use** and manufacture by primates suggest cognitive abilities that might have characterized early hominins. This is the use of a tool to obtain another object that will then serve as a tool for another goal (usually food). Mental requirements include foresight and planning of hierarchically organized behaviors. All great apes and several monkey species are capable of spontaneously using two tools in sequence, but the *Pan* species and orangutans can use as many as five. The manufacture of bush baby which are spears, for example, requires as many as five steps (Pruetz et al. 2015). Sequential tool use also requires patience, the ability to suppress immediate motivations and defer an action until appropriate preparations have been made. Patience is

required for other natural behaviors such as using a tool to withdraw termites from a nest.

## Primate Perspectives on Social Life

**Societies.** Comparison across the primates demonstrates the social ancestry of humans. A common kind of society, called a troop or community, contains multiple adult females and one or more adult males – numerous males in *Pan*, baboon, and human societies. The *Pan* species and human hunter-gatherer societies display fission-fusion: members form subgroups (“parties”) that are flexible in size and personnel; they can travel independently or coalesce. Fission-fusion organization in the spider monkeys of the New World provides a basis for analogical testing of hypotheses, such as the relationship of fission-fusion processes to food supply and other environmental conditions (Aureli and Schaffner 2010).

**Multilevel Societies.** Some primatologists see better analogies for early hominin organization in more complex primate societies that are characterized by nesting of social units within larger social units, also a characteristic of human societies (Swedell and Plummer 2019). Multilevel societies have been documented in various Old World monkeys and may occur in several New World primates. The constituent groups are one-male units (usually containing several females), which may be embedded in two more higher levels of organization. These social entities (rather than individuals) undergo fission-fusion processes. Terminological confusion has been introduced with regard to the higher levels by the cooption of terms such as “troop” and “community” that were originally coined for single-level societies such as those of baboons and chimpanzees. In addition, these terms are not used consistently across multilevel species.

Related analogies for hominins occur in a few multilevel species. One is dispersal of females from their natal groups, which converges with outmarriage of women among humans. Another is male-male tolerance between constituent units, probably mediated by kinship. These male-male

relationships are also facilitated by elaborate and repeated greeting rituals, which have been compared to certain greetings in human societies.

**Family Antecedents.** Multilevel societies offer one model for the emergence of human families within communities, but there are others. Among baboons and some other Old World monkeys, certain males and females form distinctively close relationships that persist through non-mating periods. In some species, bonding is suggested by the occurrence of affiliative behaviors such as mutual grooming and huddling. In some cases, the males provide some care for the offspring of the female, often their own as well (Fischer and Zinner 2020).

“Pair bonding” is a controversial concept that has been applied to humans and other primates, particularly certain New World monkeys (Fernandez-Duque et al. 2020). The social and sexual arrangements among those primates are diverse. Pair living seems obligatory in some species, common in others, and occasional in still others. Some are sexually monogamous, and some are not. Bonding in the sense of emotional attachment is poorly documented in the wild, but experiments with titis suggest the possibility of analogous insights into human bonds. Owl monkeys and titis show some of the highest levels of paternal care in mammals, and both live in strictly pair-living groups, an association that may provide a functional analogy for early hominin evolution.

**Social Cognition.** Primate models suggest a maximum community size of several hundred individuals for early hominins. Human capacities for social bonding and memory may have evolved in such a context. MRI research suggests that some aspects of social life in humans and other primates are rooted in homologous parts of the brain. A study of captive baboons found that those living in larger social groups had larger brains. The effect was driven mainly by white matter volume and to a lesser extent by gray matter (Meguerditchian et al. 2021). Among captive rhesus monkeys, those housed in larger groups had more gray matter in several regions of the temporal cortex. Other monkey studies demonstrated that one of these regions is involved in

responses to faces, body movements, and probably the direction of attention of other individuals.

The *social intelligence hypothesis* relates enhanced cognition to more complex and intense social life, which entails more than group size. It explains a great deal about monkeys and apes but does not distinguish cognitive features that set apes and humans apart from other primates. The key may be the slow life history associated with larger body size (van Schaik 2016). This permitted greater growth in the metabolically expensive brain over the course of prolonged neural development, resulting in natural selection for cognitive problem-solving. In this case, a single homology may have given rise to multiple parallel developments in social relationships and cognition.

**Prosocial Behavior.** Primates display several of the elements that underlie human morality, including conformity, conflict resolution, reciprocity, reactions to inequity, and empathy (Burkart et al. 2018). These elements are not distributed evenly across primate species, which suggests that they are analogous developments. They are particularly strong in marmosets and tamarins, the small monkeys of the New World. Analogy with these monkeys suggests that elements of morality evolved in the context of shared infant care. Broader comparison indicates that prosociality increases with the amount of cooperative infant care in a species. Chimpanzees score low in tests of prosociality, but they display occasional targeted helping, food sharing, alerting others to danger, and some tendency to conformity. Cognitive abilities like those of chimpanzees may have been the most important phylogenetic factor in the evolution of hominin morality: great apes recognize inequity in the value of rewards, while marmosets and tamarins do not.

**Culture.** Chimpanzees, orangutans, and some monkey species display behavioral variation across populations and societies that many primatologists call “cultural” in the sense that distinctive behaviors are shared among group members, apparently as a result of social learning. This suggests that culture was a mode of adaptation in early hominins, perhaps as far back as the LCA. For example, researchers compared chimpanzee

termite fishing across 17 locations revealing 38 different technical elements, including community-specific combinations of three to seven elements (Boesch et al. 2020). Thirty of those were not ecologically constrained, indicating that variation was cultural. The number and combination of elements shared among individuals were more similar within communities than between them, thus supporting community-majority conformity via social imitation. The researchers asserted that variation in community-specific combinations of elements parallels cultural diversity in human greeting norms or food utensil etiquette.

## Primate Perspectives on Communication

**Tactile.** Social grooming is a vital social interaction in most primate societies and is obviously pleasurable or comforting to the individuals involved. Stimulation of the skin is probably an important stimulus for those being groomed. In humans, with little body hair to groom, other kinds of touching may stimulate a tactile system that is homologous with other primates (Dunbar 2017). Social and emotional components comparable to those of primates are demonstrated by experiments with humans, including neural differentiation between affective contacts and neutral tactile sensations.

Embracing is common among male chimpanzees and between men cross-culturally. Chimpanzees embrace before and during confrontations and in other stressful situations. This is a case where other apes add little to phylogenetic reconstruction because adult male-male relations in gorillas and orangutans are largely hostile. However, embracing is a vital social behavior in spider monkeys, which live in fission-fusion societies analogous to those of chimpanzees (Aureli and Schaffner 2010). Social limitations on this natural behavior in some Western cultures may be psychologically damaging.

**Visual.** Gestures, including facial expressions and postures, are important in communication between primates (Fröhlich et al. 2019). Gestures with the arms and hands are important

components of natural visual communication among the great apes. Many of these gesture types are widely shared and thought to be homologous. Some gesture types used by human children also occur among apes and may be derived from the LCA.

“Smiling” probably conflates two expressions with separate primate origins. One is the “silent bared-teeth display” (less formally, the “grin” or “grimace”). Phylogenetic comparison shows that social submission was its original meaning and function (van Hooff and Preuschoft 2003). The other relevant primate expression is the playface, a relaxed open-mouth expression that occurs mainly in the play of immatures. It signals intent for friendly interaction and is motivated by pleasure. It is probably homologous among the great apes and humans and seems to be convergent in several other primates. An alternative view of smiling is that the two signals actually overlap in humans rather than just being conceptually conflated. They became uncoupled from their original contexts (submission and play) and converged in human evolution to the point of overlapping. Comparable uncoupling of the grimace has occurred in monkeys with relaxed dominance hierarchies that do not require sharply defined social signals.

**Auditory.** In young apes and human children, the playface is associated with laughter, i.e., vocalizations with similar acoustic features that are probably homologous and signal friendly intent even though play may become rough. Some theorists distinguish human laughter from the other primate signals, postulating that it was elaborated by natural selection to cope with short-term fluctuations in danger and hunger. In this view, laughter became a means for rapid communication of safe conditions to all members of a group (Gervais and Wilson 2005). The assumption of stressful conditions for early hominins is supported by analogy with savanna chimpanzees, baboons, and vervet monkeys.

Drumming is a natural display in wild chimpanzees. An individual pounds his hands and feet against a large tree, making a sound that carries over long distances. Captive chimpanzees and gorillas drum on artificial surfaces. Bimanual

drumming may be homologous among great apes and humans, suggesting an early origin for this component of music (Fitch 2006). Analogously, drumming by some captive macaques attracted the attention of other monkeys in a way similar to conspecific vocalizations. It also influenced viewing of conspecifics in a preferential looking experiment, and fMRI showed that drumming activated the same brain areas as vocalizations.

**Intentionality.** Primate communication displays features that are also components of language in the human sense. These have implications for the origins of human cognition. Experiments with chimpanzees demonstrated intentionality in gestural communication by documenting actions that individuals used repeatedly toward a recipient until they got a particular response (Tomasello and Call 2019). Such behavior is motorically ineffective, requires the active participation of a partner to fulfill its purpose, is tailored to the attentional state of the audience, entails waiting for the recipient's response, and often seems directed toward a single social goal. The apes account for the perceptual access of the recipient by using attention-getting gestures such as touching or moving to be in front of the intended recipient. If an initial gesture fails, the sender may persist by repetition or elaborate by sending alternative signals. One example is the use of a string of play gestures, either the same or different, until the other begins playing. Some vocalizations also hint at intentionality. Confronted by a moving snake model, wild chimpanzees called to companions, alternating gaze between the snake and the other chimpanzees, and persisted until all companions were informed.

**Conversation.** Analogy with the small-brained marmosets suggests that elements of conversation could have developed early in hominin evolution, including turn taking and voluntary control of vocalization (Ghazanfar et al. 2019). Marmosets can modulate and interrupt their own ongoing vocalizations and cooperatively modify the amplitude of calls in accord with perceived distance from each other. They take turns in contingent and repeated exchanges over extended periods, an ongoing interaction that differs from simpler call-response patterns. In addition to

facilitating communication between adults, turn taking reinforces learning of vocalizations by young marmosets. They are influenced by contingent parental feedback in much the same way as human infants.

Voluntary control of vocalization requires the involvement of various cortical structures, some of which have been connected to learning and voluntary production of primate vocalizations. A network of frontal regions that could allow such cognitive control seems to be homologous across monkey species and with humans. There is also evidence for neural similarities between humans and monkeys with regard to laryngeal control and to the processing of vocal stimuli from others.

**Multimodal Communication.** Human communication is multimodal. People combine language with nonlinguistic sounds, facial expressions, gestures, and postures, and the capacity to deliver and understand such combinations is apparent in other primates (Fröhlich and van Schaik 2018). This capability can probably be traced back to the LCA and beyond. Primates display flexibility in communication by choosing among modalities depending on circumstances. Chimpanzees and bonobos use gestures when another individual is face-to-face and touch to get the attention of one facing away. Vocalizations may be used in either situation. Making such choices might, for example, have enhanced the safety of early hominins with predators in the vicinity.

Primates also use signals from different modalities simultaneously. Lip smacking during grooming by monkeys and apes, for example, delivers auditory and visual stimuli. African apes, like humans, differ from orangutans in the use of auditory gestures, such as slapping surfaces, stamping on them, drumming, or clapping hands. Simultaneous signals may simply reinforce one another, but they may also deliver more complex meanings with social significance. Bonobos, for instance, emit the same "contest" vocalization in playful and aggressive contexts but add gestures that distinguish their intentions. These and other examples suggest that an important function of multimodal signaling is to reduce ambiguity.

The importance of multimodal combinations is indicated by the fact that chimpanzees often use them even when communication is facilitated by good visibility and familiarity between individuals. The prominence of such communication in our closest relatives suggests that a similar system aided our early ancestors in their expansion across Africa.

## Conclusion/Summary

Many behavioral scientists study nonhuman primates as models or as a source of analogies for a better understanding of our earliest ancestors. The results augment the archeological record and fill gaps where there is no record. Frameworks for such inferences include phylogenetic relationship, convergent evolution, ecological parallels, and functional necessities. Chimpanzees and baboons play leading roles in this approach, but many other primates provide useful information. Rather than result in abandonment of this approach, criticisms have stimulated more cautious and nuanced hypotheses. At the same time, findings in both paleoanthropology and primatology have strengthened the basis for inference. This work has provided insights for a wide range of behaviors, including food preferences, tool use and manufacture, social grouping, male-female relations, nonverbal communication and elements of language, and morality.

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

## Synonyms

National Primate Research Centers (NPRCs);  
Regional Primate Research Centers (RPRCs)

In 1960, the US Congress passed a legislation that enabled the National Institutes of Health (NIH) to fund and to provide resources for scientists and institutions to conduct research with nonhuman primates (“National Primate Research Centers” 2019; Newbern 2016; “Yerkes National Primate Research Center” 2019) through the National

Center for Research Resources (NCRR; Berns et al. 1996) and now through the Office of Research Infrastructure Programs (ORIP), Division of Comparative Medicine; “U. S. Department of Agriculture, Environmental Enrichment for Nonhuman Primates” 2019. The National Institutes of Health Regional Primate Research Centers program began a network of research facilities for the study of monkeys and apes. Since 2002, the facilities have been known collectively as the National Primate Research Centers (NPRC). Emory, Tulane, and Harvard universities and the universities of California-Davis, Oregon, Washington, and Wisconsin were awarded the grants and the status of Regional (and later, National) Primate Research Centers (Riopelle and Coyle 1971). After the recent closure of the NPRC at Harvard University (2015; Fountain 2013), there are currently seven centers included in this network: the California National Primate Research Center (University of California-Davis, Davis, CA), the Oregon National Primate Research Center (Oregon Health and Science University, Beaverton, OR), the Southwest National Primate Research Center (Texas Biomedical Research Institute, San Antonio, TX), the Tulane National Primate Research Center (Tulane University, Covington, LA), the Washington National Primate Research Center (University of Washington, Seattle, WA), the Wisconsin National Primate Research Center (University of Wisconsin-Madison, Madison, WI), and the Yerkes National Primate Research Center (Emory University, Atlanta, GA) (“National Primate Research Centers” 2019). Scientists at these centers strive to improve the health of humans and other animals worldwide through biomedical research with monkeys (primarily) and apes, including investigations of preventative medicine, treatments, and cures for a wide range of diseases and ailments.

## Yerkes National Primate Research Center (Atlanta, GA)

Two histories of the Yerkes NPRC – originally named the Yale Laboratories for Primate

Biology – have been written: *Yale in Florida*, an unpublished monograph by Ada Yerkes in (1939), which in turn is summarized as part of Donald Dewsbury's (2005) definitive *Monkey Farm: A History of the Yerkes Laboratories of Primate Biology, Orange Park, Florida, 1930–1965*. This history begins well before the NIH began funding the National Primate Research Centers program. In 1916, Dr. Robert M. Yerkes, a psychobiology professor at Yale University, published an article in *Science* calling for the establishment of primate research centers. Dr. Yerkes speculated that by studying nonhuman primates, a wide range of scientists could gain insight about human biology and behavior; further, he argued that this speculation was widely appreciated by others in the field, and that “the neglect by scientists of systematic study of all of the primates excepting man is due, not to lack of appreciation of their scientific value, but instead, to technical difficulties and the costliness of research” (p. 231). He further described the solution to these practical obstacles: a permanent, general-use research station or institute, located in a suitable climate, with particular types of leadership and staffing, that availed and coordinated an interdisciplinary program of research. Subsequently, Dr. Yerkes convinced Yale University as well as the Rockefeller and Carnegie Foundations to provide funding for such an institution. In 1930, Yale Laboratories for Primate Biology opened its doors in Orange Park, Florida (Dewsbury 2005).

Yale University renamed the facility the Yerkes Laboratory of Primate Biology in honor of its founder, following his retirement in 1941. After Dr. Yerkes's death (February 3, 1956), management of the research institute shifted from Yale to Emory University. Around the same time, scientists successfully developed a polio vaccine through the use of a nonhuman primate model. This discovery led to a surge of interest in nonhuman primate research and a federal ruling by the US Congress to allocate two million dollars to the NIH, so that the NIH could establish the first federally funded primate centers (Dukelow and Whitehair 1995; “Yerkes” 2019). In 1961, the NIH granted Emory University with Regional Primate Research Center (RPRC) status and

funds that enabled the move of the Yerkes Center from Orange Park, Florida to Emory's campus in Atlanta (“Yerkes” 2019). Emory also established an affiliated field station in Lawrenceville, Georgia, where behavioral and reproductive research is conducted.

Since the Yerkes NPRC opened nearly 90 years ago, the center has made many important contributions to human health research, including (but certainly not limited to) creating an AIDS vaccine that is now in clinical trials, developing a candidate medication to treat cocaine addiction, and assisting in the development of a drug that preserves kidney function and prevents rejection in organ transplant (“Yerkes” 2019). Yerkes researchers are also dedicated to studying nonhuman primate cognition and behavior. Field-changing discoveries have been reported in the famous ape-language research with Lana chimpanzee by Duane Rumbaugh and his team, which began at Yerkes, and in recent investigations by behavioral scientists like Bill Hopkins, Robert Hampton, and Frans de Waal and his collaborators at the Yerkes-affiliated Living Links Center (“Living Links” 2019). These discoveries include documentation that chimpanzees are as apt as humans at facial recognition; that chimpanzees, like humans, have culture – that is, they adopt social norms and pass down traditions; and chimpanzees are more likely to follow the example of older, higher-status individuals over inexperienced individuals (“Yerkes” 2019) and many more such examples.

Currently, the Yerkes NPRC is home to about 3,000 primates, including rhesus macaques, sooty mangabeys, squirrel monkeys, cynomolgus monkeys, and chimpanzees (“Yerkes” 2019). Since the US Fish and Wildlife Service (FWS) ruled that all chimpanzees – including captive chimps – would be classified as endangered under the Endangered Species Act, primate research centers have effectively ceased all biomedical testing on the animals (Grimm 2015). The Yerkes center continues to conduct noninvasive, behavioral research with their population of chimpanzees. Yerkes researchers often work in collaboration with the Atlanta Zoo to gather behavioral and cognitive data (Dukelow and Whitehair 1995).

## **Oregon National Primate Research Center (Beaverton, OR)**

The Oregon NPRC was the first center to be established using the NIH federal funding from the 1960 US Congressional Action (Dukelow and Whitehair 1995). Construction of the facility began in 1962 (Doughman 2019; Dukelow and Whitehair 1995); however, Oregon's monkeys arrived in the USA well before the research facility was established. In the 1950s, the founding group of rhesus macaques was brought to Brown University from their natural range in Asia, and they were transferred to the Oregon primate research center in 1964. That same year the government of Japan donated 46 Japanese macaques to Oregon, because the species was threatened by deforestation and by farmers who wanted to protect their crops ("Oregon National Primate Research Center" 2019). Shortly thereafter, Oregon became the first of the RPRCs to use outdoor breeding facilities (1970; Doughman 2019), and the university pioneered the social housing of nonhuman primates in the 1970s ("Oregon" 2019) including 81-acre corrals holding up to 250 animals each (Doughman 2019). The ONPRC continues to work toward improving and innovating nonhuman primate housing, for example, by recently developing PENS (Primate Enclosure in a Natural Setting) that give animals indoor-outdoor access, with housing that includes heated floors and misting for seasonal weather fluctuations (Doughman 2019). Since 1998, the ONPRC has been affiliated with Oregon Health and Science University.

The ONPRC have made several important contributions to the scientific community. For example, ONPRC researchers developed mitochondrial replacement therapies that could prevent the transfer of mitochondrial defects from mother to child. They also were able to revert a skin cell back to its embryonic state, demonstrating future potential to use patients' own cells to create new liver, heart, and other cells, greatly reducing risk of transplant rejection. The ONPRC also created monkey models that allow the scientists to explore the effects, complications, and possible prevention of several human afflictions,

such as "high-fat diet-induced obesity" as well as the effects of alcohol- and drug-using mothers on their fetuses' brain and lung development ("Oregon" 2019) and many other contributions.

The ONPRC, located in Beaverton, OR, is currently home to about 5,000 nonhuman primates. Rhesus macaques constitute the largest colony, followed by Japanese and cynomolgus macaques, and a smaller number of baboons and squirrel monkeys ("Oregon" 2019). Most of the macaques were bred on site from the 1964 founding colonies (Doughman 2019).

## **Washington National Primate Research Center (Seattle, WA)**

It was originally planned that the Washington Primate Center would be the first to be established using the NIH federal funding; however, after some maneuvering by the House and Senate Appropriations Committee, the WaNPRC was established at the University of Washington shortly after the Oregon institution's establishment in 1962 (Dukelow and Whitehair 1995). In 1970, the University of Washington founded the Infant Primate Research Laboratory (IPRL) – the only one of its kind in the nation – in collaboration with the WaNPRC (Burbacher et al. 2013). The IPRL employs infant macaque models to investigate questions related to behavioral and biological development (Burbacher et al. 2013).

In the 1980s, the WaNPRC established another important partnership. With the continued use of monkey models on HIV and AIDS-related research, it became clear that there was need for the establishment of a captive virus-free population of monkeys, so as not to deplete natural primate populations. In 1982, Dr. O. A. Smith (a member of the WaNPRC and the World Health Organization) and other members of the World Health Organization met with the Indonesian government to discuss on establishing a monkey breeding facility on Tinjil Island that would eventually become the first Primate Research Center in Indonesia (Kyes et al. 1997). The WaNPRC received their first group of monkeys from Tinjil Island in 1991 for use in AIDS-related research,

and they continue to collaborate with this field station today (Kyes et al. 1997).

The WaNPRC has made several important discoveries that benefit the health of humans and other animals, including, but not limited to, the following examples. For instance, the WaNPRC researchers successfully treated color blindness in two squirrel monkeys with gene therapy. They also created a device that reduces or eliminates vertigo for patients with Meniere's disease, and the device has potential to treat other balance disorders in the future. Scientists at the WaNPRC also researched rewiring of the brain to bypass paralysis and remobilize paralyzed limbs, and in 2008 they developed a neurochip device (currently in use in the Seattle area) that treats patients with cerebral palsy and brain injury ("Washington National Primate Research Center" 2019a). Currently, the WaNPRC is working to develop an animal model to study the genesis of HIV-fighting antibodies. The WaNPRC has also established a Tissue Distribution Program (TDP) that provides nonhuman primate tissues and biological materials to research institutions within and outside the WaNPRC ("Washington National Primate Research Center" 2019b).

The WaNPRC is in Seattle, Washington, and conducts research on approximately 3,500 nonhuman primates. Those primates are located across two UW locations and four off-site locations ("Washington" 2019a), including a recently established (2013) pathogen-free breeding colony of pigtail macaques in Mesa, Arizona ("Washington" 2019b). In addition to pigtail macaques, the WaNPRC also works with long-tailed and rhesus macaques and squirrel monkeys ("Washington" 2019b). The WaNPRC also has a conjoint research program with the Woodland Park Zoo in Seattle ("Primate Info Net" 2019).

### **Wisconsin National Primate Research Center (Madison, WI)**

The Wisconsin NPRC was established in the early 1960s shortly after the ONPRC and the WaNPRC (Dukelow and Whitehair 1995) with the University of Wisconsin-Madison (UWM) as its host institution. However, the University of Wisconsin's history of nonhuman primate

research predates the establishment of the WNPRC. In 1930, Harry Harlow founded the Psychology Primate Laboratory (also known as the Harlow Center for Biological Psychology; "Primate Info Net" 2019; "Harlow Center for Biological Psychology" 2019). In 1958, Harlow conducted his famous Nature of Love experiment at the laboratory, where he demonstrated that maternal comfort and companionship are critical to healthy development in infant macaques (Harlow 1958). Harry Harlow eventually became the first director of the WPRC ("WNPRC" 2019). Today, Harlow's Center for Biological Psychology exists as a separate but affiliated entity to the WNPRC ("Harlow Center for Biological Psychology" 2019).

Scientists at the WNPRC have made several important contributions to human and other animal health research. In 1984, the WNPRC produced the first in vitro-fertilized monkey in the world ("WNPRC" 2019). The WNPRC was also the first to produce pluripotent stem cells from monkeys (1995) and then humans (1998; "Primate Info Net" 2019). This led to the eventual first successful culturing of blood, heart, and brain cells from embryonic stem cells in the early 2000s ("WNPRC" 2019). NPRC researchers also discovered certain developmental origins of insulin resistance and obesity and, relatedly, developed an FDA-approved natural sweetener for those trying to reduce sugar intake in their daily diets ("WNPRC" 2019). The WNPRC also created new and improved drugs to protect patients from transplant rejections and autoimmune diseases ("WNPRC" 2019) along with many other important contributions.

The WNPRC is located in Madison, WI, and houses approximately 1,500 animals, including its own breeding colonies. Presently, the animals include rhesus and cynomolgus macaques and common marmosets. In the past, the center has also conducted research with stump-tailed macaques, cotton-top tamarins, and vervet monkeys ("WNPRC" 2019).

### **California National Primate Research Center (Davis, CA)**

The California NPRC was the original "national center" and was established in the early 1960s

along with the other primate research centers. It was at first designated primarily to be a breeding facility (“UCDavis California National Primate Research Center” 2019). The center was formerly known as the National Primate Conditioning Center (Dukelow and Whitehair 1995), and then the National Center for Primate Biology (“UCDavis” 2019), until its status eventually changed to the California RPRC, corresponding to the other NIH centers, and became a national institution again in 2002 when all of the regional centers were redesignated as NPRCs (“UCDavis” 2019; “Yerkes” 2019). The CNPRC is affiliated with the University of California-Davis.

The CNPRC has made important contributions to biomedical research since its opening in the early 1960s. Scientists at the CNPRC developed tenofovir (PMPA), the most commonly used anti-HIV drug worldwide. This drug leads to large medical advancements for HIV-infected people, allowing them to live longer, healthier lives and enabling HIV-positive mothers to give birth to virus-free infants (“UCDavis” 2019). The CNPRC also discovered that tobacco-smoke exposure and pollution adversely affect organ development and that formula-fed infants are more likely to develop health issues later in life than breast-fed infants (“UCDavis” 2019). The CNPRC has also made advancements in research on Alzheimer’s disease, including the development of therapies currently in clinical use with patients with the disease, among many other contributions.

The CNPRC is located in Davis, CA, and is home to approximately 4,500 monkeys, which are mostly bred on site. The majority of these monkeys are rhesus macaques, but the CNPRC also houses a small population of South American titi monkeys (“UCDavis” 2019).

### **Tulane National Primate Research Center (Covington, LA)**

The Tulane NPRC opened in November of 1964, originally with the name Delta

Regional Primate Research Center, associated with the host institution of Tulane University (“Tulane National Primate Research Center” 2019). The center is situated on a historic 500-acre property known as Alexiusville that was purchased from the Alexius family in 1962. An original building (the “Alexius House,” built in the early 1800s) still exists on the property and will eventually be used as a visitors’ center after restorations (“Tulane” 2019).

Over its history, the TNPRC has made several important contributions to biomedical science. They developed the first macaque model of heterosexual transmission of SIV (simian immunodeficiency virus; the nonhuman primate version of HIV), the first monkey model of malaria in a pregnant female, the first nonhuman primate model of celiac disease, and the first rhesus monkey model of Lyme disease and placental transmission of CMV. Scientists at the TNPRC also made significant discoveries regarding the origin of AIDS: specifically, they found that SIV is evolutionarily much older than originally believed and that the sooty mangabey monkey is the natural host of SIV and the most likely source of HIV-2. They have developed and tested (or are in the process of developing and testing) several vaccines, including a tuberculosis vaccine and an AIDS vaccine. The TNPRC also established an improved diagnostic test for Lyme disease, among many other contributions (“Tulane” 2019).

The TNPRC is located in Covington, LA, and houses nine different species of primates: squirrel monkeys, baboons, vervet monkeys, mangabey monkeys (sooty and white-crowned), patas monkeys, and cynomolgus, pig-tailed, and rhesus macaques (“Tulane” 2019). The TNPRC mostly uses rhesus macaques for their research and has their own breeding colony of rhesus macaques on site (“Tulane” 2019). The current number of nonhuman primates living at the TNPRC is not listed. In 2006, they reportedly housed approximately 4,500 monkeys; however, approximately 50 of the monkeys accounted for in that report are species that are no longer listed on the TNPRC website (“Primate Info Net” 2019; “Tulane” 2019).

## **Southwest National Primate Research Center (San Antonio, TX)**

The Southwest NPRC is the only center open today that was not one of the original institutions established in the 1960s. The SNPRC joined the list of National Primate Research Centers funded by the NIH in 1999 and is affiliated with the Texas Biomedical Research Institute (Texas Biomed; “Southwest National Primate Research Center” 2019). However, Texas Biomed was not new to join in on biomedical primate research. In 1941, Tom Slick, Jr. – a 25-year-old man who strongly believed that scientific research was the key to human progress – established the Foundation of Applied Research (“Texas Biomedical Research Institute” 2019). The foundation’s name was changed to Southwest Foundation for Research and Education in 1952, and then the Southwest Foundation for Biomedical Research in 1984, and, finally, the Texas Biomedical Research Institute in 2011 (“Texas Biomedical Research Institute” 2019). The Texas Biomedical Research Institute brought numerous research strengths, including the world’s largest captive baboon population, to the NPRC program when it joined in 1999 (“Southwest Foundation houses newest NIH primate center” 1999).

Texas Biomed and the SNPRC have had many scientific breakthroughs that have improved human and animal health worldwide. Their scientists produced the high-frequency ventilator, a device that assists premature babies’ breathing and has saved thousands of lives and reduced lung damage in the infants. They also developed surfactant – a natural product now given to all premature infants – which prevents lung damage complications in instances of premature births. Much of the development and testing of the first hepatitis B vaccine (and later, an improved Hep B vaccine) was carried out on Texas Biomed chimpanzees (“Southwest Foundation houses newest NIH primate center” 1999; “Southwest National Primate Research Center” 2019). Researchers at this institute also developed a protein mixture that can greatly reduce the recovery time for broken bones or bone restructuring,

among many other scientific contributions (“Southwest” 2019).

The SNPRC is located in San Antonio, TX, and houses approximately 2,500 nonhuman primates, including baboons, macaques (bred onsite), marmosets, and chimpanzees. The vast majority of the animals at this institute are baboons (approximately 1,100; “Southwest” 2019). In addition to the world’s largest colony of baboons for biomedical research, the SNPRC also has the largest population of aged (>10 years) marmosets in the country, with more than 70 at their center (“Southwest” 2019). Since the FWS ruling in 2015, the population of more than 100 chimpanzees housed at the SNPRC are no longer used for biomedical research. In 2016, SNPRC announced its plan to retire their chimpanzees to Chimp Haven, a national chimpanzee sanctuary in Keithville, LA, as space becomes available (“Southwest” 2019).

## **Controversies and Closures**

Whereas the National Primate Research Centers have made many scientific contributions that have changed the course of human health history, they are also shrouded in controversy. The New England Primate Research Center, hosted at Harvard University in Southborough, MA and one of the original seven institutions funded by the NIH, announced its impending closure in 2013, eventually shutting down in 2015 (Fountain 2013). Harvard cited financial reasons for closing the primate center (Fountain 2013); however, others claimed that violations of the Animal Welfare Act, as cited by the US Department of Agriculture (USDA), contributed to the decision. These issues included a federal investigation into the deaths of 16 primates at the facility between 1999 and 2012 (Fountain 2013; Johnson 2015).

## **Other Primate Research Centers**

Although the seven centers currently funded by the NIH may be the highest-profile primate research centers in the USA, dozens more exist

in both the USA and abroad. The European Union funds its own network of nine primate research institutions, including the Centre Nationale de la Recherche Scientifique (CNRS) in France (“Primate Info Net” 2019). Though not part of the EU network, the Max Planck Institute is a distinguished, well-renowned, and widespread primate research organization located in Germany (“Max-Planck-Gesellschaft” 2019). The Max Planck Institute is a nonprofit organization with 84 institutes and research facilities and more than 23,000 employees (“Max-Planck-Gesellschaft” 2019). Also of note, the Primate Research Institute of Kyoto University (Japan) conducts behavioral, cognitive, biomedical, and other types of research on its primates, including an indigenous species, the Japanese monkey (“Primate Research Institute Kyoto University” 2019).

In the USA, other centers receive funding from the NIH but do not have the NPRC status. One such example is the University of Puerto Rico’s Caribbean Primate Research Center (CPRC), located on the island of Cayo Santiago. Researchers at the CPRC often conduct naturalistic, observational research on their native population of rhesus macaques. Another example is the University of Oklahoma Health Sciences Center in Oklahoma City, OK, and its affiliated baboon breeding facility in El Reno. The Oklahoma centers conducted biomedical research on their non-human primates, such as vaccine development and advancement of neuroprosthetics, until its announcement in 2015 that the program would be shut down by 2019. The university president claimed the closure was due to a shift in the university’s research priorities and a desire to reallocate the university’s funds (Knittle 2015a); however, the announcement came shortly after a high-profile USDA report revealing the death and mistreatment of several monkeys under OU’s care (Knittle 2015b).

Further examples of NIH-funded centers include the Alamogordo Primate Facility (APF), the National Center for Chimpanzee Care (NCCC), and the New Iberia Research Center (NIRC), all of which once housed chimpanzees for use in biomedical research. After the

2015 ruling to list all chimpanzees as endangered under the Endangered Species Act, effectively ending all invasive biomedical research on chimpanzees, the APF, the NCCC, and the NIRC had to either relocate or commit to the husbandry and care of the chimpanzees for the rest of their days.

The Alamogordo Primate Facility houses still over 100 chimpanzees and is located on the Holloman Air Force Base in Alamogordo, New Mexico. The center had been conducted aeronautical and space research with its animals since the 1950s, but in 2001 the NIH assumed ownership of the chimpanzees after the APF repeatedly violated the terms of the Animal Welfare Act. In 2011, after a public outcry when the NIH tried to transfer the chimpanzees to the SPNRC, the APF discontinued all invasive research on their chimpanzees; 126 chimpanzees continue to live out their days at APF but are not involved in any invasive research. Similarly, a colony of over 100 chimpanzees is cared for by the University of Texas MD Anderson Cancer Center’s National Center for Chimpanzee Care, and the animals engage only in noninvasive behavioral studies. The current research goal of the NCCC is to improve welfare and husbandry practices for captive chimpanzees. Likewise, in 2016, the University of Louisiana at Lafayette’s New Iberia Research Center, once the largest chimpanzee research facility in the nation, announced its plan to relocate all of its chimps to a chimp haven (known as Project Chimps) in Blue Haven, GA. The NIRC continues to conduct biomedical and behavioral research with its 6,000 other nonhuman primate residents, including rhesus, pig-tailed, and long-tailed macaques, African green monkeys, and brown-tufted capuchins.

Some primate research centers, such as Georgia State University’s Language Research Center (LRC; “Language Research Center” 2019) in Atlanta, GA, and the Ape Cognition and Conservation Initiative (ACCI; “Ape Cognition and Conservation Initiative” 2019) in Des Moines, IA, have historically conducted exclusively noninvasive research with their animals and have continued that trend to this day. Scientists at the LRC and the ACCI investigate

cognitive and behavioral questions rather than biomedical ones. From the 1970s to 2016, the NIH funded ape-language research and other cognitive studies at the LRC, focused on humans, chimpanzees, bonobos, rhesus macaques, and brown-tufted capuchins. Research on cognition and social behavior in monkeys and continues at the LRC, whereas the language-trained ape Kanzi and his family of bonobos have moved to ACCI where they continue to participate in behavioral research.

## Primate Sensory Systems

Laura M. Bolt  
Department of Anthropology, University of  
Waterloo, Waterloo, ON, Canada

## Synonyms

Audition; Catarrhine; Communication; Gustation; Haplorhine; Haplorhini; Hearing; Hominoid; Mammal; Olfaction; Platyrrhine; Prosimian; Seeing; Senses; Sensing; Smell; Sound; Strepsirhine; Strepsirhini; Tactile; Taste; Touch; Vision

## Definition

Primates are mammals with complex and large brains compared to body size and traits including an enhanced sense of touch, increased reliance on vision, and reduced reliance on sense of smell compared to other mammals. Their sensory systems allow them to perceive and interpret the world around them, and include vision (sight), olfaction (smell), gustation (taste), audition (hearing), and tactile systems (touch). Each of these sensory modalities contain adaptations that help primates to survive in a range of habitats including arboreal environments. Through the information provided by their sensory systems, primates can find food, avoid predators, and effectively perceive and interact with other individuals of their species.

## Introduction

The primates are an order of eutherian (placental with advanced development before birth) mammals comprised of strepsirrhines (suborder *Strepsirrhini*: lemurs, lorises, galagos, and pottos) and haplorhines (suborder *Haplorhini*: tarsiers, Old and New World monkeys, apes, and humans). They diverged from other mammals approximately 80–90 million years ago, and today have approximately 504 living species (Estrada et al. 2017). Compared to other mammals, primates are characterized by having larger brains compared to body size, brains with greater complexity, clavicles which allow a broader range of motion, generalized dentition enabling a broader diet, five fingers and toes including opposable thumbs and big toes in many species, power and precision grips, fingerprints, toeprints, and palm prints, nails instead of claws, and forward-facing eyes with binocular vision. These characteristics are thought to be adaptations for arboreal (tree-living) environments, with the earliest primates and many extant primates living primarily in trees (Smith 1924). Many of the traits typifying the primate order reflect differences in sensory adaptations between primates and other mammals. For example, primates have an enhanced sense of touch due

to their fingerprints and nails, while their five digits including opposable thumbs and big toes enable them to grip and manipulate objects in the environment with greater strength and precision (Liman 2006). Primates also rely less on olfaction and more on vision than other mammals. Their front-facing eyes with overlapping fields of vision allow them to see and interpret their surroundings reliably in three dimensions (Liman 2006). These visual and tactile adaptations give primates survival advantages, allowing them to interact with their environments in new ways, while their larger and more complex brains help primates process the additional sensory information received more efficiently. Compared to other mammals, primate brains have particularly enlarged occipital and parietal regions, which are linked to their greater reliance on vision and touch (Liman 2006).

Primates are also uniquely social among mammals, with the majority of primate species living in mixed-sex groups that stay together on a year-round basis (Dunbar 2010). In solitary species, primate sensory systems are adapted to help individuals better navigate diverse habitats and access food resources while avoiding predators. In group-living species, the complexity of primate sensory systems may additionally help facilitate ongoing social contact between conspecifics. Primate vision, olfaction, audition, and sense of touch are especially important for social relationships, with information about other group members obtained through the senses. Visual, olfactory, gustatory, auditory, and tactile senses work together in primates to help them perceive their environments more effectively and to communicate with other members of their species. The complexity of primate sensory systems may be understood as a series of adaptations that enhance primate ability to interact with their environments and with conspecifics.

## Vision

### Primate Stereoscopic Vision

Primates are characterized by their stereoscopic (binocular) vision, with overlapping fields of vision from each forward-facing eye creating a

wide visual field of three-dimensional depth perception (Liman 2006). Stereoscopic vision is a sensory trait that has evolved multiple times, in evolutionary lineages as divergent as cephalopods (Class *Cephalopoda*) and vertebrates (Nityananda and Read 2017). While binocular vision is not unique to primates, having the combination of forward-facing eyes plus stereoscopic vision (stereopsis) is thought to be rare in vertebrates, and is only found in some birds (e.g., birds of prey, Order *Accipitriformes*), mammalian carnivores (Order *Carnivora*), and primates (Nityananda and Read 2017). The combination of forward-facing eyes plus stereopsis allows for a larger stereoscopic visual field than found in animals with side-facing eyes (Nityananda and Read 2017). While a wider stereoscopic visual field helps birds of prey and carnivores be more successful in hunting prey, it also leads to enhanced fitness for primates. As arboreal mammals, primates rely on their binocular vision to travel, find food, and evade predators while remaining in the treetops. The arboreal hypothesis suggests that primate traits including improved stereoscopic vision and increased grasping power evolved as adaptations for life in the trees, allowing primates better ability to perceive distance and therefore to travel between branches without falling (Smith 1924). An alternate hypothesis relates to visual predation and suggests that primate traits including improved binocular vision and fine motor skills evolved to facilitate the hunting of insects, which were likely a key food source for early primates (Cartmill 1992). As small-bodied prey that may move quickly in any direction in three-dimensional space, insects would have been difficult to catch without good depth perception (Cartmill 1992). A third hypothesis relates to angiosperm (flowering plant) evolution and suggests that traits like better vision and improved gripping ability of hands and feet are adaptations that allow primates to more successfully feed on fruit at the end of small branches (Sussman 1991). Regardless of the selective pressures that led to the development of a wider stereoscopic visual field and other derived traits in primates, excellent binocular depth perception is a ubiquitous component of visual systems in living primates.

Stereoscopic vision helps individuals across species travel efficiently through both arboreal and terrestrial (ground-based) environments, find food, avoid predators, and interact with conspecifics.

### Primate Color Vision

Some primates also have color vision. Color vision depends on the ability of retinal photoreceptors (rods and cones) and the brain regions associated with seeing to perceive different wavelengths of light, then to compare them to one another. Retinal rods allow organisms to see their surroundings under low light conditions, such as at night, while cones increase visual perception during brighter conditions, such as during daylight (Bowmaker 1998). Vertebrate eyes have rods and cones with different types of opsin, the photopigment that enables eyes to perceive different types of light wavelength and to see in color. Color vision evolved in fish and reptiles during early vertebrate evolution, but some retinal cones were lost during the evolution of mammals, likely due to the earliest mammals being nocturnal (Bowmaker 1998). As early mammals adapted to using their visual systems primarily at night, their visual acuity in low light levels was enhanced by reducing their color vision to a dichromatic (two light wavelength ranges) system (Liman 2006). This dichromatic system allowed them some color vision but limited their perception to only two light wavelength ranges, short (sensing blue light) and long (sensing red and green light without being able to differentiate between them) (Bowmaker 1998). A dichromatic vision system is still present in most living mammals, but trichromatic (three ranges of light wavelength) color vision evolved again in the primate order. Along with marsupials (Infraclass *Marsupialia*), primates are the only mammals in which some species possess three types of retinal cone (Bowmaker 1998). Trichromacy enables some primates to perceive three different light wavelength ranges in comparison to one another; in addition to short (sensing blue light) and long (sensing red light) wavelengths, trichromats can also perceive medium (sensing green light) wavelengths (Carvalho et al. 2017). This gives

trichromat primates the ability to tell the difference between red and green and therefore to see in full color.

Primates are characterized by this increased ability to see in color compared to other mammals, while still maintaining a wide variation in color perception ability across taxa. Their range of ability to perceive color is thought to be adaptive given the varying light conditions that primates live in, with some primates being nocturnal (active at night), some being diurnal (active during daylight), and some being cathemeral (active across the diel cycle) (Liman 2006). Some extant primates can perceive three different light wavelength ranges (red, green, and blue) and can see in full color (trichromats), others can perceive two different light wavelength ranges (red, plus blue or green) and see in partial color (dichromats), and some can perceive only one light wavelength range (red) and do not see in color (monochromats) (Carvalho et al. 2017). Old World monkeys, apes, and humans (catarrhines, Parvorder *Catarrhini*), and one genus of New World monkey (platyrrhine, Parvorder *Platyrrhini*), the howler monkey (*Alouatta* spp.), are trichromats and consistently able to see in full color (Liman 2006). In most other New World monkeys and some lemur species, females are able to see in full color if they have a specific genetic polymorphism on an X chromosome. However, males and other females in these species lack this gene and are dichromats who cannot differentiate between red and green colors (Liman 2006). Lemur species where females have this trichromat polymorphism include some sifaka and ruffed lemurs (*Propithecus* spp. and *Varecia* spp.) and the red-fronted lemur (*Eulemur rufifrons*), all of which are diurnal or cathemeral (Carvalho et al. 2017). However, most diurnal and cathemeral primate species are consistent dichromats, including nearly all New World monkeys and most lemurs. Monochromat primates can see light, dark, and shades of grey, but no color. Monochromat primates are all nocturnal and include strepsirrhines such as lorises and galagos (*Lorisidae* and *Galagidae* families), lemurs including fork-marked lemurs (*Phaner* spp.), fat-tailed dwarf lemurs (*Cheirogaleus medius*), and

hairy-eared dwarf lemurs (*Allocebus trichotis*), and one genus of New World monkey, the owl monkey (*Aotus* spp.) (Carvalho et al. 2017).

The differences in both activity patterns and dietary preferences among extant primates may explain the persistence of these differences in color perception. Nocturnal primates who are monochromats may be insectivorous (i.e., eat insects as a primary dietary resource) and better able to detect the movement of insects in a low-light environment due to their lack of color perception (Carvalho et al. 2017). In contrast, primate trichromats who are frugivorous or folivorous (i.e., eat fruit or leaves as a primary dietary resource) may be better able to locate red or yellow fruits or young leaves against a background of green vegetation during daylight (Carvalho et al. 2017). Finally, primate dichromats may have a range of dietary adaptations but be better able to find camouflaged or hidden prey than those with full color vision under certain light conditions (Carvalho et al. 2017).

### Other Primate Eye Adaptations

Living primates also show variation in other features associated with visual perception in low- and high-light levels. Like most other vertebrates, nocturnal primates have *tapetum lucidum*, an eye tissue covering which reflects light backwards through the photoreceptor layer and toward retinal cells, causing reflective eye shine and providing greater visual sensitivity in low-light levels (Ollivier et al. 2004). With the exception of a few diurnal brown and ruffed lemur species (*Eulemur* and *Varecia* spp.), living lemurs, lorises, galagos, and pottos have *tapetum lucidum*. However, all haplorhines lack this structure, despite the tarsiers and one New World monkey genus (owl monkey, *Aotus* spp.) being nocturnal (Ollivier et al. 2004). In contrast, haplorhine eyes have fovea, which are small pits in the center of the retina that improve central vision and color perception, particularly during daylight. Lemurs and lorises, which are more likely to be active in low light levels, generally lack retinal foveae (Ross 2004).

### Olfaction

Although primates are characterized by their increased reliance on vision as a sensory modality compared to other mammals, olfaction is still an important mode of perception, especially for strepsirhines. While primate snout length is reduced and primate faces are flattened compared to other mammals, strepsirhines have longer snouts than haplorhines as well as *rhinaria* (wet noses), enabling olfactory organs to get better exposure to potential scent compounds in the environment (Epple 1986). Strepsirhine brains also have larger olfactory bulbs than haplorhines, attesting to the greater importance of this sensory system in lemurs, lorises, galagos, and pottos compared to other living primates. Across taxa, primate olfactory ability is characterized by sensitivity, meaning that all primates can detect odors when at low levels in the environment. Primates are also adept at discriminating between odors, meaning that they can easily tell the difference between different chemical compounds based on scent. In both strepsirhines and haplorhines, smell is enabled by the main and accessory olfactory systems. The main olfactory system allows perception of volatile airborne compounds that might elicit a response from many different animals, such as the esters of ripe fruit. In contrast, the accessory olfactory system perceives more particular nonvolatile compounds emanating from conspecifics, such as pheromones (Liman 2006). The vomeronasal organ (VNO) is the accessory olfactory organ and is located in the nasal septum in vertebrates including some reptiles and mammals including primates. While it is vestigial (nonfunctional) in catarrhines, it is more functional in tarsiers and New World monkeys and is still fully operational and widely used by strepsirhines (Epple 1986).

Primate sense of smell is important for both ecological and social reasons. Across taxa, primates use odor to detect desirable foods (e.g., sugary, fleshy fruit). For example, lemur species including the mouse lemur (*Microcebus murinus*) and diademed sifaka (*Propithecus diadema*) and New World monkeys including the white-faced capuchin (*Cebus capucinus*) and Central American

spider monkey (*Ateles geoffroyi*) use odor to find food items ranging from insects to flowers to ripe fruit for consumption (Nevo and Heymann 2015). Olfaction is also a key component of the social behavior of strepsirhines, tarsiers, and New World monkeys. Urine is used as a type of scent mark in some of these primate groups through urine washing, a behavior where primates direct their urine streams back toward their bodies, then use it to mark substrates like tree branches (Delbarco-Trillo et al. 2011). Urine washing is thought to be especially important in solitary and nocturnal strepsirhines like lorises, galagos, and pottos, while group-living, diurnal lemurs are more dependent on glandular scent secretions (Delbarco-Trillo et al. 2011). Odor is produced by scent glands in various primate body areas, primarily in the genital, sternal, and brachial regions, although scent glands may also be present in palmar, antebrachial, forehead, and chin regions in some species (Epple 1986). Solitary species, like lorises, galagos, pottos, and some lemurs, rub their scent glands on substrates that can retain odor for hours or days, likely lasting until other individuals of the same species pass through the area. These scent marks may signal territory occupancy or sexual receptivity to conspecifics (Delbarco-Trillo et al. 2011). In group-living primate species, scent secretions have myriad social uses. The ring-tailed lemur (*Lemur catta*), for example, uses scent marks for a range of functions, including indicating territorial boundaries, establishing dominance rank (Kappeler 1998), advertising female estrus, and displaying the quality of potential mating partners (Walker-Bolton and Parga 2017). In New World monkeys such as the moustached tamarin (*Saguinus mystax*), scent marks are similarly used for identifying social group members and potentially receptive mating partners (Heymann 1998).

## Gustation

Primates rely on their sense of taste to help them select nutritious food items and reject harmful substances. Taste bud receptor cells convey information to the brain through gustatory nerves, allowing primates to obtain sensory information

about items in their mouths. Through the sensory taste buds, details are provided about the temperature, texture, and composition of potentially edible items. Primates can perceive tastes including sweet, salty, umami (savory), bitter, and sour; they demonstrate general affinities for some tastes (sweet, salty, umami) but aversion for others (bitter, sour) (Liman 2006). Taste preferences show clear fitness benefits, with foods high in nutritive content usually featuring preferred sweet, salty, and/or umami tastes (Liman 2006). Primate avoidance of bitter and sour tastes is adaptive in preventing them from ingesting harmful or poisonous substances, such as spoiled food or plant toxins like tannins and alkaloids (Liman 2006). Across primate taxa, taste receptors show similarities but also some differences, with tasting perceptions more alike in closely related species and less alike in more distantly related groups. For example, Old World monkeys like the olive baboon (*Papio anubis*) and pigtailed macaque (*Macaca nemestrina*) showed greater preference for sour tastes than New World monkeys like the common squirrel monkey (*Saimiri sciureus*) and Central American spider monkey (*Ateles geoffroyi*) (Laska et al. 2003).

## Audition

Primates use hearing to navigate their habitats and to monitor for the presence of predators, prey (e.g., insects), and conspecifics in the area around them. Most natural sounds are made by living organisms as they vocalize or move through their environments, and being able to perceive and interpret these sounds is a key component of primate survival (Heffner 2004). Greater hearing sensitivity is linked to greater social complexity in most mammals, and primates also share this tendency (Ramsier et al. 2012). Similarly to other mammals, all primates have good sound localization ability (i.e., ability to detect where sound is coming from) and can hear low-pitched sounds at and below 125 Hz (Heffner 2004). Although primate species across taxa can generally hear low frequencies, large-bodied primates like Old World monkeys, apes, and humans tend to perceive a

range of frequencies (sound pitches) that is lower than smaller primates. Conversely, smaller-bodied primates such as New World monkeys, tarsiers, and strepsirrhines have hearing ranges that perceive generally higher pitches, with some even perceiving and making ultrasonic vocal sounds (Ramsier et al. 2012). This correlation between relative body size and auditory frequency hearing range is a general pattern seen throughout mammals (Heffner 2004) and may be optimized for perception of species-specific vocalization frequency ranges as well as for sound localization in very small species. The generally strong ability of primates to localize sound is thought to be adaptive given their forward-facing eyes and narrower range of vision compared to other mammals (Heffner 2004). When they hear an unexpected noise, primates need to know the direction in which to turn their head in order to see what is creating the auditory disturbance and to then make the decision to flee if necessary.

Primate auditory systems are well-adapted to respond to potential threats. In addition to perceiving noises that predators make through movement and vocalization, group-living species have also evolved alarm calls, which are used to alert other group members to the presence of a threat in the area (Ramsier et al. 2012). Many social species across taxa have also evolved referential calls, meaning that vocalizations refer to a specific predator type (i.e., snake or eagle) or a predator's direction of approach (i.e., terrestrial vs. aerial). Primates ranging from lemurs (e.g., ring-tailed lemur, *Lemur catta*; Bolt et al. 2015) to New World monkeys (e.g., white-faced capuchin, *Cebus capucinus*; Digweed et al. 2005) to Old World monkeys (e.g., vervet monkey, *Chlorocebus pygerythrus*; Seyfarth et al. 1980) are known to have referential predator vocalizations that conspecifics hear and respond to, even when predators are not visible.

All living primates use vocalizations to communicate, including both solitary and group-living species. Vocalizations allow individuals to stay in touch with conspecifics even when out of visual range, such as in dense forest

environments. Solitary species generally have smaller vocal repertoires than social species, but both use sound to convey information about the occupancy of an area, likely to prevent competition by spacing out individuals and groups (Ramsier et al. 2012). Group-living species have larger repertoires and greater vocal complexity, mirroring the larger range of ecological and social interactions that they engage in with conspecifics (Ramsier et al. 2012). In addition to predatory threat response, primates may vocalize to avoid separation from social groups, to maintain proximity to preferred companions within groups (e.g., contact calls, Bolt and Tennenhouse 2017), to advertise the location of food resources to other group members (e.g., food calls, Heffner 2004), to defend mates, rich food resources, or territories from other groups (e.g., long calls, Bolt et al. 2019), or to establish dominance ranks and attract mates through honest displays (e.g., advertisement calls, Bolt 2013). This reliance of primate social behavior on sound-based communication has shaped primate auditory systems, ensuring that primates can hear each other in addition to environmental stimuli.

## Tactile System

Primates have an enhanced sense of touch and better grip capability compared to other mammals. This impacts their ability to find and ingest food, to make and use tools, to socialize at close range, and to travel, particularly in arboreal environments. In contrast to other mammals, primates have dermatoglyphs (distinctive lines, whorls, and ridges on fingers, toes, and the palms of hands and feet), pentadactyly (five fingers and toes), and nails instead of claws in most species, which work together to give primates greater sensitivity in perceiving the properties of objects and substrates in their environments. Primates also have opposable thumbs, divergent big toes, and power and precision grips, which give them better ability to manipulate their environments through strength and dexterity. Power grips involve simultaneous

grasping by the digits and the palm, thus applying force from the whole hand or foot to manipulate objects. In contrast, precision grips involve fine-motor skill interactions with pressure applied by individual digits to a small area, thus manipulating objects with accuracy and control. All primates have robust power grips, while precision grips are better developed in monkeys, apes, and humans than in strepsirhines. The interaction between these two types of grip capability along with primates' more refined sense of touch enables a broader range of social, locomotory, and foraging behaviors than seen in most other mammals.

Touch is important in primate social behavior, with prolonged tactile contact (e.g., resting while in body contact) and grooming (manipulation of the fur using hands or teeth) being key components in maintaining inter-individual relationships and in reducing individual stress levels (Dunbar 2010). Social grooming (grooming another individual) is important in group-living species, while both group-living and solitary species engage in self-grooming. In monkeys, apes, and humans, greater manual dexterity has led to more grooming using the hands, while strepsirhines use toothcombs (dental structures with outward-facing front teeth) to groom themselves and others (Dunbar 2010).

Their ability to touch and grip enables primates to travel effectively through arboreal environments; for example, by using branches and vines as supports, by leaping between trees, and by balancing at the ends of small branches without falling to the ground (Smith 1924; Sussman 1991). The fingers, toes, and palms of their hands and feet are hairless with textured skin ridges and whorls (dermatoglyphs) to increase friction and gripping power during movement between substrates. Some New World monkeys have additionally evolved prehensile tails, which are arboreal adaptations for dense forest environments. These are also seen in some other mammals, particularly those endemic to South America (e.g., opossums, Order *Didelphimorphia* and anteaters, Suborder *Vermilingua*). Prehensile tails act as extra limbs, providing further gripping power for arboreal

monkeys and increasing their ability to locate and harvest food while suspended in the trees.

Increased sensitivity, dexterity, and strength in hands and feet also mean that primates should be able to make and use more sophisticated tools than other animal species, and tool use is present in living primates ranging from some strepsirhines (e.g., brown lemurs, *Eulemur* spp.) to New World monkeys (e.g., capuchins, *Cebus* spp.) to catarrhines (e.g., macaques, *Macaca* spp.; baboons, *Papio* spp.; great apes, *Gorilla* spp., *Pongo* spp., and *Pan* spp.; Bentley-Condit and Smith 2010). Among other functions, primates use tools to acquire hidden or inaccessible food sources. For example, primates employ hammers and anvils to crack open nuts (e.g., common chimpanzees, *Pan troglodytes*; capuchin monkeys, *Cebus* spp.; macaques, *Macaca* spp.; Bentley-Condit and Smith 2010). They also utilize modified sticks to harvest termites, ants, or bees from inside mounds (e.g., common chimpanzees, *Pan troglodytes*; Sumatran orangutans, *Pongo abelii*; Bentley-Condit and Smith 2010). Primates may also use their hands and feet to harvest foods like insects or small vertebrates that are hidden in tree holes, palm fronds, or under bark. These uses of tools and digits substantially improve primate extractive foraging ability, thus increasing the range of ecological niches that primates can inhabit and demonstrating the strong adaptive function of the enhanced primate tactile system.

## Conclusion

Primates rely on their sensory systems for both environmental and social reasons; they use their senses to perceive food, predators, and their habitats, and to interact with conspecifics. Their large and complex brains with highly developed sensory abilities give them adaptive advantages, with a reduced sense of smell and enhanced vision and touch compared to other mammals allowing them to occupy new roles in their environments. The sophistication of primate sensory systems is

foundational to the behavioral and ecological intelligence of this mammalian order.

### Introduction

Most primates live in social groups and a remarkable variety of social organizations can be observed among species. These different types of organization may constrain the structure of social relationships within groups. For instance, in the primate order, group size range from a few individuals as in some lemur species, tarsiers (*Tarsius*) or gorillas (*Gorilla*), to hundreds of individuals as in mandrills (*Mandrillus sphinx*) or geladas (*Theropithecus gelada*, Mitani et al. 2012). As a consequence of this wide range, communication and interactions between individuals will vary greatly according to the number of available partners and will result in different social structures among species.

There is also a variety in the flow of individuals between groups, defining different dispersal patterns. In some species, males disperse and thus ensure gene flow between groups, such as in macaques (*Macaca*), baboons (*Papio*), or gorillas, while in other species only females will be able to emigrate, as in chimpanzees (*Pan troglodytes*) or bonobos (*Pan paniscus*, Smuts et al. 1987). Social relationships will then not be established in the same way between individuals with a limited interaction time available and others that will be together all their life.

As a result of this variety in group size and dispersal modes, primate species exhibits different grouping patterns and can be classified in five types: solitary, pair, one-male-multifemale group, multimale-multifemale group, and multimale-one-female group. For example, some species will form groups that include several families, such as chimpanzees, bonobos, or many

cercopithecine species, while others will constitute solitary family clans, such as gorillas (Smuts et al. 1987) or callitrichines. However, while most species exhibit uniform social organizations, some others present considerable variations between populations, resulting in different social structure within the same species (Mitani et al. 2012).

Finally, important differences in grouping dynamics can also be noted. Many primate species have stable social groups over time, such as cercopithecines for instance (Smuts et al. 1987). Conversely, some species such as chimpanzees or bonobos have a fission-fusion-like organization characterized by the formation of temporary parties (Aureli et al. 2008). This instability over time may also impact the distribution of social relationships within groups as well as maintenance strategies.

The establishment and maintenance of social relationships within groups will enable individuals to live together and better cope with daily pressures they might experience. The social structure of a population is then shaped by the balance between within-group competition among individuals for the access to food resources or sexual partners, and cooperation needs to answer to environmental pressure (i.e., predation) but also between-group competition.

### Definition

Before looking at the variety of primate social structure and the parameters underlying this variety, it is important to define what is a social structure. Hinde (1976) proposed a hierarchical bottom-up model via dyadic social interactions that determine social relationships whose patterns draw the social structure of a group. The base level of this model is thus dyadic social interactions, defined as the behaviors emitted by two or more individuals toward others at a given time. These interactions have a concrete reality for the animal, since it is the expression of its behavior in the present, and they are observable directly by an external observer. The second level characterizes the social relationships between individuals,

which correspond to repeated and consistent interactions in time observed between these individuals. Finally, the social structure, third level in Hinde's model, gathers all the social relationships existing between group members and thus forms a social network.

Kummer (1968) added a functional dimension to Hinde's model and proposed that social relationships increase the predictability of a dyadic interaction outcome, facilitating social interactions between individuals. Repeated and consistent interactions over time can then lead to stable and valuable relationships between individuals, allowing them to develop social strategies like food sharing, cooperative hunting or agonistic support (Cheney and Seyfarth 2007). Investing in stable relationships may then benefit to individuals as it increase the likelihood that the partners behave in a positive way in return.

Social relationships and social structure are not directly observable but are inferred from the repeated observation of social interactions (Hinde 1976; Kummer 1968). They are often considered as an abstract representation, resulting from the analysis of the distribution of interactions, and the question of the ability of animals to represent these structural levels can then be asked (Barrett and Henzi 2002).

Indeed, to enable understanding and assimilation of social relationships, animals must be able to recognize group members and memorize past interactions, whether they involve them directly or not (Cords 1997). Experiments in primates have revealed knowledge of the relationships that may exist between members of a group in some species (Seyfarth and Cheney 2012). In long-tailed macaques (*Macaca fascicularis*), for example, individuals are able to discriminate pairs of related individuals from unrelated pairs. Macaques have also been shown to be able to differentiate dominant and subordinated individuals in a pair of familiar congeners. Another experiment in chacma baboons (*Papio ursinus*) also showed that females were aware of the dominance link between two individuals, and responded more strongly to inconsistent situations with the group dominance hierarchy. In this same species, the loss of an affiliated individual following a predation event will cause a drastic increase

in the general level of stress in comparison with other individuals not facing the loss of a close social partner (Engh et al. 2006).

Thus, knowledge of these relationships between group members allows individuals to predict the outcome of an encounter or interaction with other individuals (Kummer 1968). This memory gives the animals the ability to develop social strategies based on these social relationships, thus enabling them to acquire survival and/or reproduction advantages (Cheney and Seyfarth 2007).

## Types of Social Relationships

Social relationships are defined as a function of the type, frequency, intensity, and quality of social interactions between individuals. We distinguish three types of interactions: affiliative (indicating a spatial association), affiliative (friendly), and agonistic (including aggressive and submissive behaviors).

Affinitive and affiliative interactions such as body contact, social grooming, and affiliative facial expressions are usually considered together to deduce affiliative relationships. Social grooming in particular is known to be very important for the establishment and maintenance of strong affiliations between two individuals (Dunbar 2010). All these interactions will then define affiliative relationships between individuals, and the distribution of these relationships will depend on the considered behaviors. Indeed, individuals who are strongly affiliated in the context of social grooming may not necessarily be as strongly affiliated when only considering body contact for example. Affiliative relationships are thus made up of a set of interaction networks drawn from different socio-positive behaviors (Dunbar and Schultz 2010). It is thus important to take these different networks into account while studying the social structure of a group.

Affiliative relationships are rarely distributed in a homogeneous way within a group, and privileged relationships between certain pairs of individuals may appear. For instance, yellow baboons (*Papio cynocephalus*) and chacma baboons interact preferentially with a limited

number of preferred partners, and these privileged relationships are stable over time (Seyfarth and Cheney 2012). The quality of the relationship is evaluated on the basis of past interactions between individuals, and a preferred relationship will be reinforced as the interactions continue. Affiliative relationships can also be assymetric, with one partner being primarily responsible for maintaining the bond (Mitani et al. 2012). However, biological market theory suggests that social grooming could be exchanged for itself or for other commodities such as support during conflicts (Noë and Hammerstein 1995). It is thus necessary to consider all the different aspects of affiliative relationships while studying reciprocity.

Group living does not only involve positive interactions between individuals. Indeed, the proximity of individuals sharing similar nutritional needs but also targeting the same sexual partners leads to conflicts between group members (Krause and Ruxton 2002). Thus, individuals will interact agonistically within group, and the sum of these negative interactions enables to distinguish asymmetric relationships of dominance: some group members take the ascendancy more regularly over others during conflicts and are then considered as dominant, while losers being referred to as subordinated (de Waal and Luttrell 1989). In most species, dominance relationships are described using ranking methods, forcing individuals into a linear dominance hierarchy, determined from agonistic interactions (de Waal and Luttrell 1989). Individuals are then ranked in a dominance hierarchy (Appleby 1983) that can be described by its linearity, transitivity, and steepness. More recently, the concept of social power has been used to describe the “degree of implicit agreement or consensus among group members about whether an individual is capable of successfully introducing force into polyadic agonistic situations” (Thierry et al. 2004). This concept seems to be particularly crucial to understand dominance relationships in species such as chimpanzees (*Pan troglodytes*), macaques, and baboons displaying ritualized status signaling outside of agonistic contexts, like submissive behaviors for example. This nonaggressive signaling strategy allows individuals to express their hidden

power or their knowledge of their status, reducing the risk of conflict and injury (Mitani et al. 2012).

Depending on the characteristics of dominance and social power of a species, different dominance style can be described. For example, we can differentiate egalitarian from despotic societies. While in despotic societies, agonistic relationships are clearly defined and dominance hierarchy is highly linear, egalitarian societies displayed absent or poorly defined agonistic relationships and the dominance hierarchy is unclear and non-linear. Dominance relationships will be less important in the social structure of the group in egalitarian species than in despotic ones. It is also possible to distinguish species exhibiting tolerant versus intolerant styles. This degree of tolerance has a direct impact on the frequency of bidirectional conflicts, injuries, or submissive behaviors (Thierry et al. 2004). If egalitarian species are usually tolerant, despotic ones can either display intolerant or tolerant styles. Dominance style has been intensively studied in macaques, and it is possible to rank the different species along a gradient from highly despotic/intolerant to highly egalitarian/tolerant (Thierry et al. 2004).

These dominance relationships are very important for the individuals’ lives as it influence certain behaviors such as social grooming, access and monopolization of food resources, or individuals’ spatial distribution.

## Parameters Underlying Social Structure in Primates

### Kinship

In primates, kinship constrains some of the affiliative and agonistic relationships presented in the previous section (Chapais and Berman 2004). In many species, several families live together within the same group, forming multi-family groups. Depending on the dispersal patterns (male or female philopatry), we observe male or female clans. In some species, kinship accentuates social relationships between individuals who will express stronger affiliative behaviors for their relatives; this is called nepotism. For example, social grooming is more frequent between female relatives in rhesus macaques

(*Macaca mulatta*). Formation of coalitions and/or alliances during conflicts is also more frequent between individuals belonging to the same matriline in this species (Thierry et al. 2004). Kin display more appeasement and reconciliation behaviors after conflicts in many macaque species (Thierry et al. 2008). Finally, this kinship bias may also be observed in the case of food sharing in some species, with males sharing food more often with their relatives in chimpanzees for instance (de Waal and Luttrell 1989).

Concerning dominance relationships, kinship can be a key parameter underlying the dominance hierarchy. Indeed, in some species displaying a female philopatry, an entire maternal lineage can be dominant over the others, and dominance rank is then transmitted from mother to daughter (Thierry et al. 2004). This is observed in a lot of cercopithecines such as vervets (*Chlorocebus pygerythrus*), baboons, rhesus, and Japanese macaques (*Macaca fuscata*).

However, even if genetic kinship is classically used to establish the links between individuals, we usually cannot distinguish genetic link from familiarity that an individual develop with his relatives. Indeed, during his development, a juvenile spends most of his time with his mother and her kin and does not establish relationships with other group members until later (Mitani et al. 2012). The kinship effect could then be the result of the familiarization process of the individual during his development, constrained by the biological needs of the offspring, instead of the recognition of his relatives.

Moreover, it is important to consider kinship not only from the philopatric-sex side but also from the dispersal-sex side. It has been shown in rhesus macaques, baboons, mandrills, and sun-tailed monkeys (*Cercopithecus solatus*), species displaying a female philopatry, that affiliative interactions were significantly higher among paternal siblings than among unrelated dyads (Mitani et al. 2012).

### Age and Sex Composition

In addition to the kinship network, two other parameters are known to influence group social structure: individuals' age and sex. These two

parameters are demographic and represent individuals' intrinsic characteristics. In the majority of social primate species, groups are composed of individuals that vary greatly according to these two parameters, conferring them different needs in terms of nutrition, activity, and experience. These differences can then impact the time that each individual devote to social interactions with the rest of the group but also shape within-group competition for valuable resources, and thus influence the social structure that results from these interactions.

Age has a strong influence on certain social behaviors. For example, age may affect agonistic relationships, with young individuals usually having a lower dominance rank than old ones. However, in classical female philopatric groups such as in macaques or baboons females usually outrank their oldest sisters, model also known as the "youngest sister ascendy rule" (Mitani et al. 2012).

The sex of the individual may also influence the distribution of these relationships between group members since social interactions will be more frequent between individuals of the same sex in most species (Mitani et al. 2012). This sexual segregation can be very extreme: unisex groups are observed outside breeding seasons in some mandrill populations where females may band together to counter male aggression (Abernethy et al. 2002, Setchell et al. 2006). Conversely, in other species such as hamadryas (*Papio hamadryas*), females interact almost exclusively with males, which are at the center of harems, the basic social unit that characterizes this species (Kummer 1968). In chacma baboons, these strong social bonds between males and females allow females to reduce the probability of infanticide when an emigrant male arrives or when changes in the dominance hierarchy occur (Engh et al. 2006).

### Diversity of Social Structures in Primates

Demographic parameters such as age, sex, or kinship can strongly impact the distribution of relationships within primate groups. Depending on

species, group composition according to these parameters is different and will thus constitute a panel of possible combinations, resulting in very different social structures (Kappeler and van Schaik 2002; Mitani et al. 2012). The following section is not exhaustive and will focus on well-documented examples among colobines, cercopithecines, and apes.

### Colobines

Colobine groups vary in size and composition, from pairs and dependent offspring to one-male/multifemale groups to large multimale-multifemale groups. Dispersal patterns vary between species, including male dispersal and female philopatry, female dispersal and male philopatry, and dispersal by both sexes (Mitani et al. 2012). Adult females form stable affiliative relationships, which are stronger between kin. Even in case of female dispersal, it is not rare to find female kin in the same social group as they might join the same group after dispersion (Mitani et al. 2012). Adult females usually form a clear and linear dominance hierarchy, which is not based on kinship but on age: young females are dominant over old ones. Dominance rank can change frequently and females do not form coalitions to maintain their rank. Colobine females are usually tolerant and reconcile very frequently after conflicts, especially with close affiliates (Arnold and Aureli 2007).

Most colobines (African *Colobus*, Asian *Presbytis*, and *Trachypithecus*) live in one-male groups, but multimale groups are found in *Procolobus*, *Nasalis*, *Rhinopithecus*, some *Colobus*, and Hanuman langurs (*Simia entellus*). In these multimale societies, dominance hierarchy among males is linear and high rank gives access to receptive females. Males use policing behaviors to reduce aggression frequency and severity between females when the competition level is high. Very little is known about male-male affiliative relationships in colobines (Mitani et al. 2012).

### Cercopithecines

All cercopithecines live in social groups, ranging from less than 5 individuals in DeBrazza's

monkeys (*Cercopithecus neglectus*) to several hundreds in mandrills and geladas. However, typical group size ranges from 10 to 100 individuals in most species. Cercopithecines societies are characterized by female philopatry and male dispersion, leading to groups structured around matriline: female kin form strong and stable affiliative relationships (Mitani et al. 2012). Coalitions between matriline members are frequent, and depending on the tolerance level between adult females, dominance hierarchy may be matrilineal. However, in extremely tolerant species such as Tonkean macaques (*Macaca tonkeana*) with a weak dominance hierarchy, it is common to observe strong social bonds distributed even between unrelated females (Thierry et al. 2004).

The number of adult males in cercopithecine groups is partly determined by the number of adult females: small groups usually have only one adult male, while groups with more than 5 females become multimale (Andelman 1986). Male-male competition for the access to sexual partner is high, leading to frequent agonistic interactions. Stable affiliative relationships between males are rare. However, male coalitions can be observed between subordinated to gain access to higher ranks or receptive females such as in geladas, baboons, sooty mangabeys (*Cercocebus atys*), and several macaque species (Mitani et al. 2012). Coalitions can also be observed when extra-group competition is intense.

In most cercopithecine species, male-female affiliative interactions are mainly observed during reproduction season, and the level of interactions during the rest of the year is highly variable. In mandrills and talapoins (*Miopithecus talapoin*), males usually join groups only when females are receptive. In guenons (*Cercopithecus*), patas (*Erythrocebus patas*), and vervets, males stay in the group the whole year but are peripheral outside reproduction season. In baboons and macaques, males and females may form cross-sex stable friendships with valuable partners. This strategy ensure mutual agonistic support but also offspring's protection against other males in baboons (Mitani et al. 2012). A more extreme male-female bond type can be observed in gelada societies, exhibiting a multilayered

organization. Indeed, geladas are characterized by strong and stable male-female affiliative relationships as they live in one-male units (OMUs). Several OMUs may group to form bands, which aggregate to a third level of organization called herds. Composition of bands and herds might vary frequently while OMUs are very stable (Swedell 2010).

Finally, hamadryas baboons constitute a remarkable exception to the classical "cercopithecine model" as we observe male philopatry and female dispersal in this species. Hamadryas societies exhibit a multilevel organization in which small OMUs are parts of clans, which may aggregate to form larger bands. In these OMUs, adult males force females into strong and stable affiliative relationships through coercion, even outside breeding seasons. Females within a harem are not related and may develop stable social bonds. Male kin are highly tolerant toward each other within bands (Smuts and Smuts 1993).

## Apes

With only a limited number of species, apes present a wide variety of social organization, resulting in very different social structures. Orangutans (*Pongo pygmaeus*) do not form stable social groups and spend most of their time feeding alone due to a high level of competition over food resources (Wrangham 1979). Individuals' interactions are rare and limited to female-female and male-female contacts. Female-female interactions reflect a certain level of familiarity, while male and female meet only during the reproductive season. Adult males are extremely hostile toward each other, especially flanged males that defend their home range (Smuts et al. 1987).

Adult female gorillas form stable groups with their dependent offspring and one or two adult males, which are usually close relatives (Smuts et al. 1987). Adult males are dominant over adult females and maintain very strong affiliative bonds. Subordinated males may engage frequently in grooming interactions with adult females as it can influence female dispersal in case of group fission. Agonistic interactions are rare between dominant males and females and are frequently followed by reconciliation initiated by

females (Watts 1995). Interactions between males can be aggressive, especially between adults, but coalitions are rarely observed (Smuts et al. 1987). In case of multifemale groups, competition for food access is low and agonistic interactions are rare and usually bidirectional. Adult females may form affiliative relationships, especially between relatives in mountain gorillas (*Gorilla beringei beringei*, Watts 1995). This kinship effect is weaker in western gorillas (*Gorilla gorilla*), due to female dispersal (Mitani et al. 2012).

Chimpanzees live in multimale-multifemale groups with a fission-fusion social organization. As males are philopatric in this species, male-male social bonds are stronger than female-female or male-female relationships (Mitani et al. 2012). The dominance hierarchy in adult males is linear and clear, and competition to access to high ranks is intense, as high-ranking males are more attractive to females and grooming partners, and have privileged access to food resources. Males may form both short-term and long-term alliances to help maintaining their rank (Newton-Fisher 2004). Despite male philopatry, kinship has a weaker influence than age in the distribution of affiliative relationships: males from the same age-cohort maintain stronger bonds than relatives (Mitani et al. 2012). Indeed, as females disperse in this species, adult males may not have a lot of relatives in their group. Adult males interact with adult females mostly during swelling periods, but males may develop stable affiliative relationships with kin-related females, such as mother and son for instance (Goodall 1986). Competition between adult females to get access to food resources and sexual partners is high, and immigrant females will face aggression from resident ones. Except during these immigration events, coalitions between adult females are rare. However, they may form affiliative relationships by frequent grooming interactions and co-participation to parties. Depending on the level of competition for food resources, adult females may form a linear dominance hierarchy, but not in all populations (Mitani et al. 2012).

Bonobos have a very similar social organization and social structure to chimpanzees. However, the level of competition for food resources is lower and adult females develop stronger

affiliative relationships than adult males (Parrish 1996). Females are also less aggressive while new individuals enter the group, protecting them from male harassment. Adult males form a clear and linear dominance hierarchy, but they do not form alliances to maintain their rank (Mitani et al. 2012). Outside of reproductive contexts, male and female kin such as mother and son or sister and brother may form strong social bonds and alliances, helping males to maintain their dominance rank. Unlike chimpanzees, adult females may be dominant over adult males in bonobos, especially when having female coalitions (Mitani et al. 2012).

## Primate Suspensory Behavior

Kevin D. Hunt

Anthropology Department, Indiana University,  
Bloomington, IN, USA

### Synonyms

Arm-foot hanging; Arm-hanging; Brachiation; Clambering; Quadrumanous locomotion; Transferring; Tree-swaying

As arboreal animals, primates face a locomotor and postural challenge terrestrial animals do not: moving or posturing among small-diameter, irregularly placed, uneven, and unstable supports. Some mammals manage by digging their claws into the surface on which they are climbing, but this strategy only works when the support is large compared to the animal. Some mammals that utilize this strategy, like squirrels, negotiate small branches relying on good balance to compensate for their inability to grip supports, but their “scrambling” locomotion is clumsy compared to primates. Primates have gripping hands and feet that allow them to negotiate small branches by gripping the supporting branch with long,

dexterous fingers and toes. Unlike other mammals, which typically confront compliant branches during travel, primates gather food among smaller branches; thus they both spend more time in this context, and they require a stable positioning that frees a hand to pluck food.

While this strategy works for many small supports, among still smaller-diameter branches, as small as the thickness of their finger, maintaining balance requires extreme muscular exertion or—on extremely compliant branches—walking on top is utterly impossible: such tiny twigs bend under an animal’s weight until they are vertical. Suspensory primates give up on sitting, standing, and walking and instead swing underneath these flexible supports to hang by their arms, their legs, or both. While the body weight of the sitting primate pushes food away from them, it pulls it toward the suspensory primate (Grand 1972; Fig. 1). Suspensory primates have a more flexible gathering scheme because they can feed both on top of branches and below, doubling their feeding space from a hemisphere to a sphere (Fig. 2; after Grand 1972).

A second challenge for arboreal primates is *gap-crossing*. While the large branches, boughs, and boles near the tree center offer firm enough support to allow a stable base for leaping, near the tree edges smaller branches and twigs—the part of the tree specialists refer to as the terminal branches—are too flexible (or compliant) to withstand the forces exerted on them. Here all but the smallest primates face the same limitations as when primates sit to feed among small branches: the branches bend until vertical. As with sitting, hanging underneath these small twigs offers a solution. The primate must then reach out to branches from the neighboring tree while suspending itself and then gradually transfer weight. Orangutans commonly, but other apes seldomly, use their large mass to sway a tree back and forth until they can reach a support in a neighboring tree.

While every species is unique, there are four principal suspensory modes among the primates, an inverted quadrupedalism often referred to as (1) *slow climbing*, (2) *hindlimb suspension* (often assisted by the tail) which is principally postural mode, (3) *clambering* (locomotion only) or

**Primate Suspensory Behavior, Fig. 1** Suspensory behavior precludes the need to balance on top of unstable supports but requires a strong grip

**Primate Suspensory Behavior, Fig. 2** Suspensory behavior doubles their feeding space

*quadrumanous suspension* which is a non-stereotyped combination of arm and leg suspension commonly engaged in only by orangutans, and (4) *unimanual suspension* that, when locomotor, is referred to as *brachiation*.

A third of the members of the superfamily Lorioidea are *slow climbers*. Their inverted walking behavior is slow and deliberate, a stealthy movement that aids their stalk-and-pounce insect-predation adaptation (Fig. 3). All the lorisoids

**Primate Suspensory Behavior, Fig. 3** Pottos often engage in slow-climbing suspensory behavior

move on top of branches in the same slow manner, moving one hand/foot at a time, giving priority to stability and reducing perturbations to their support over speed while reducing perturbations to their support (Walker 1969), the slender loris more so, the potted and slow loris less so. Slow climbers rarely leap and do not run. They progress by shifting one hand or foot at a time, leaving the other three limbs securely gripping the support (Cartmill and Milton 1977). Slow-climbing species have fore- and hindlimbs of approximately equal length. They have rotatable wrists that allow them to orient their hands to any angle a support might offer, an adaptation that allows them to avoid lunges, leaps, and other jerky movements that vibrate supporting branches (Cartmill and Milton 1977).

Howler monkeys and some lemurs, the ruffed lemur in particular (Meldrum et al. 1997), hang from their hindlimbs, often assisted by the tail in howlers and spider monkeys (Fig. 4). Spider monkeys and their relatives may dispense with the feet altogether and hang by the tail alone (Fig. 5). Spider monkeys, but not howlers, often assist forelimb suspension (Fig. 5) with their powerful prehensile tail. Spider monkeys and their close relatives do not have particularly long forelimbs, at least not compared to apes, and they utilize quadrupedal walking more often than do apes (Larson 1998; Fleagle 2013).

The apes, members of the superfamily Hominoidea, often engage in suspension that involves the forelimbs alone (Fig. 6). Chimpanzees, gibbons, and siamangs feed among small branches using *unimanual suspension*, or one-armed suspensory posture also known as *arm-hanging*. The high frequency of this behavior among these apes requires specialized adaptations, including narrow scapulae and cranially oriented glenoid fossae (tilted-up shoulder joints).

Orangutans have extremely flexible hips, allowing them to engage in suspensory behavior using any combination of hands/feet with the torso held in an upright or vertical orientation (Fig. 7). The locomotor version of this behavior is called *clamber*. Because this behavior involves both hands and feet, it is sometimes called *quadrumanous*, or four-handed, locomotion or posture. Arm-hanging is quite common, but not nearly as common arm-foot hang, a posture in which the body is suspended from an arm and leg on the same side.

An important locomotor behavior for orangutans is *tree-swaying*, a mode that begins with a clinging posture on a near-vertical support; by oscillating the body back and forth, the orangutan causes the tree bole to sway, bringing a target support in a neighboring tree within reach, after which suspensory or quadrumanous posture and

# Primate Suspensory Behavior,

**Fig. 4** Hindlimb suspension in lemurs (left) and spider monkeys, assisted by the tail

**Primate Suspensory Behavior, Fig. 5** Tail suspension in the spider monkey and tail-assisted forelimb suspension

locomotion complete the transfer between canopies.

*Brachiation* is a type of rapid and graceful suspensory locomotion that might be considered a locomotor version of arm-hanging in that the body swings forward like a pendulum, suspended first from one arm and then the other (Fig. 8).

Swinging under “monkey bars,” a playground apparatus similar to a horizontal ladder, is the human version of this behavior. This locomotion makes up a large proportion of the locomotor behavior of the lesser apes, the gibbons, siamangs. Their brachiation is so quick and acrobatic that they even propel themselves through the air with a

**Primate Suspensory Behavior, Fig. 6** Unimanual suspension in the gibbon; the forelimb is often assisted by one or more hindlimbs

**Primate Suspensory Behavior, Fig. 7** Torso-orthograde (upright) quadrumanous suspensory posture (left) and arm-foot hanging (right) in the orangutan

period of free flight, a behavior so unique that some specialists prefer to limit the term brachiation to the lesser apes alone. While capable of a near-gibbon-like brachiation, the heavier great apes engage in brachiation much less often, and when they do brachiate, it is a slower, more deliberate behavior. A lunging sort of brachiation, in which an individual reaches out to grasp branches

in a neighboring tree, after which it transfers weight onto the new supports, is called *transfer-ring*; this positional mode is the last phase of tree-swaying (see above).

All apes have mobile shoulders, a broad thorax, completely extensible elbows, long fingers, rotatable wrists, arms longer than legs and lack tails.

**Primate Suspensory Behavior, Fig. 8** Gibbon brachiation

While all primate locomotion is influenced by the demands of feeding, this is particularly so for the apes. Apes are dependent on ripe fruit, and such fruits are often found in the small, peripheral branches of trees where supports are small and flexible. While supporting branches are small, the great apes have the largest body mass of the primates. The combination of a small-branch feeding regime and great body weight encourages suspension during feeding, rather than sitting or quadrupedal walking, which is the typical monkey feeding behavior. Apes spend so much time among the terminal branches of trees not because they prefer it, but because they must. This is demonstrated by comparing the behavior of high- to low-ranking males. Low-ranking males arm-hang from small-diameter, compliant branches when in the tree periphery; high-ranking males monopolize the few large-diameter branches available in the tree periphery, and they feed while sitting (Figs. 9 and 10) (Hunt 2016).

Because suspensory behavior solves a specific challenge – the need to negotiate small-diameter, flexible (or compliant) supports typically found among the outermost branches of trees – for the larger apes, the size of branches on which they position themselves dictates when suspensory behavior occurs. For example, among chimpanzees, suspensory locomotion makes up only 0.2% of all locomotion, but its frequency rises to 29.4% in the outermost meter of the tree canopy; 8.8% of this suspensory behavior is brachiation and 20.6% is torso-erect transferring. As with locomotion, suspensory posture, too, is more common the smaller the support. Arm-hanging makes up 2.5% of behavior among supports greater than 10 cm, 8.3% of behavior among 3–10 cm supports, and 24% of behavior when supports are less

**Primate Suspensory Behavior, Fig. 9** Among chimpanzees the frequency of suspensory locomotion increases dramatically in the tree periphery, within 1 m of the tree edge, from 0.2% in the tree core to 29.4% in the tree periphery

**Primate Suspensory Behavior, Fig. 10** Among chimpanzees the frequency of suspensory posture increases as support size decreases, from 2.5% of behavior among branches greater than 10 cm to 8.3% among intermediate supports to 24% among branches <3 cm

than 3 cm. Similar trends are seen among the other apes (Hunt 2016).

Australia

Introduction

Primates are a group of eutherian mammals that contain lemurs, lorises, tarsiers, monkeys, apes, and humans. They lack many specialist features and as a result show a wide range of morphological, behavioral, and ecological flexibility. For example, while most primates are arboreal, some taxa are terrestrial. Diet in primates is also quite variable ranging from folivorous to frugivorous to

insectivorous with multiple combinations of each occurring both across and within species. In terms of locomotion, some groups specialize in vertical clinging and leaping to move between trees while some climb on branches slowly on all fours. Still some swing between the branches while others move across the ground using knuckle walking. Morphological variation also exists with the smallest species (mouse lemur) weighing only 30 g with the largest species (male eastern lowland gorilla) weighing up to 250 kg.

With all this variation, it begs the questions, what unifies primates? What features do they have in common that allow for them to be classified under the same order? This is not necessarily easy to answer, but there are a few categories of traits that can be used to distinguish primates from other mammals including: (1) grasping hands and feet, (2) big brains, (3) increased visual system, and (4) generalized skeleton and dentition. Within each of these broad categories, there are distinct features that are seen among primates (Table 1). It is generally accepted that these traits reflect an adaptation to living in the trees, which was the ancestral environment for primates. It is important to note that not all primates have all these features and some of them are shown in variable degrees.

**Primates, Table 1** Features that distinguish primates from other mammalian orders

| Categories of primate traits       | Features within each category                                                                                                                                                                                             |
|------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Grasping hands and feet            | Opposable thumb and big toe, pentadactyly, finger nails instead of claws, power and precision grips                                                                                                                       |
| Big brains                         | Big brains relative to body size, slower rates of development, expanded neocortex                                                                                                                                         |
| Increased visual system            | Forward facing eyes and associated stereoscopic vision, less reliance on smell and associated decrease in olfactory centers in the brain, flatter faces, trichromatic color vision (in catarrhines and some platyrrhines) |
| Generalized skeleton and dentition | Retention of clavicle, retention of two bones in the forelimbs, increase in truncal uprightness, reduction in the number of teeth                                                                                         |

For example, not all primates have fully opposable thumbs with some taxa (i.e., lemurs and lorises) showing a pseudo opposable thumb and some taxa (i.e., tarsiers and marmosets) showing no opposability in their thumb at all.

## Primate Taxonomy

Given the amount of variability in primate characteristics, coming up with a unified system for primate classification has been difficult and there has been considerable revision to primate taxonomies over time. It is generally agreed that all primates arose from a common ancestor roughly 80–90 million years ago and then underwent a proliferation during the Eocene (Martin et al. 2007). This resulted in the formation of many of the current living lineages discussed below. While current taxonomy agrees that primates are divided into two suborders: Strepsirrhini, which is composed of Lorisiformes (galagos, pottos, lorises), and Lemuriformes (Malagasy lemurs); and Haplorrhini, which includes tarsiiiformes (tarsiers), and Simiiformes (further broken down into the parvorders platyrrhines (New World monkeys) and catarrhines (Old World monkeys, apes, and humans)); it took hundreds of years to arrive at this categorization.

### History of Primate Taxonomy

Many iterations of primate taxonomy have been suggested over the years dating back nearly 300 years. In 1735, Carolus Linnaeus published his infamous *Systema Naturae*, and it was in the 10th edition of this book that he recognized primates as one order of mammals including four genera – *Homo*, *Simia*, *Lemur*, and *Vespertilio*; although as the latter included bats, it was removed by future taxonomists who also split *Simia* and *Lemur* into a variety of genera. Work through the remainder of the 1700s included that of Cuvier, Huxley, and Geoffroy Saint Hilaire (just to name a few) who continued to describe new species of lemurs and monkeys. By the mid-1800s, many of the primate species were known and described with a taxonomy that was relatively agreed upon. It was then not until the

1970s that tree shrews were removed from the primate order when genetic evidence revealed them to be less related to primates than to squirrels (order Dermoptera). This left Primates to be divided into two monophyletic groups: Prosimii and Anthropoidea. Prosimians included lemurs, lorises, galagos, and tarsiers, and Anthropoids included monkeys, apes, and humans. The contentious issue with this classification was the placement of the tarsiers, which although share many primitive characteristics in common with lorises and lemurs, including nocturnality, mobile ears, and an enhanced sense of smell, also exhibit Anthropoid characteristics such as a lack of nocturnal eye morphology. While their position within primate taxonomy was left up to debate for many years, it came to rest in the 1980s with the proliferation of genetic methods and techniques that allowed for more testing of individuals and species that revealed despite the morphological and behavioral similarities to lemurs and lorises, tarsiers are more similar genetically to monkeys, apes, and humans. This then led to the development of a new classification system that suggested that primates still be divided into two suborders, however, that these be Strepsirrhini (lemurs and lorises) and Haplorrhini (tarsiers, monkeys, apes, and humans), which is still the classification system used today.

### Current Primate Taxonomy

See Fig. 1

### Strepsirrhini

Strepsirrhine primates, known as the tooth-combed primates, are generally agreed to fall into two infraorders: Lemuriformes (Malagasy lemurs) and Lorisiformes (lorises and galagos). While there has been some suggestion that the lemur family, Cheirogaleidae should in fact be a third infraorder (Chiromyiformes); genetic data does not support this and show that Chiromyiformes fit better within the Lemuriformes (e.g., Chatterjee et al. 2009). Genetic data also suggests that Strepsirrhines

        - Superfamily Hominoidea
          - Family Hylobatidae (3 genera)
          - Family Hominidae (5 genera)

initially split into Lemuriformes and Lorisiformes some 75 million years ago (Perleman et al. 2011). Some of the features which unify Strepsirrhines include a wet nose (rhinarium), a tapetum (reflective lucidum layer in the eye to improve nocturnal vision), large eye orbits including a postorbital bone that runs around the socket, an increased reliance on smell and enlarged olfactory lobes in the forebrain, independently mobile ears and a tooth comb. Behaviorally, while some lemurs are diurnal, the majority of Strepsirrhines (and all lorisiformes) are nocturnal, which is the ancestral condition.

### Lemuriformes

Lemuriformes are endemic to Madagascar and while the fossil record of Madagascar is currently limited to the past 15,000 years, the presence of a

tooth comb like African Strepsirrhines suggests that they have been present on Madagascar since the Eocene. Genetic data also suggests lemurs have been separated from their mainland African counterparts for 75 million years. It is thus proposed they migrated to Madagascar, which has been an island for over 100 million years, during a rafting event at some 50–80 million years ago (Ali and Huber 2010). Due to their isolation on Madagascar, they have evolved many traits that are unusual among primates including torpor in some nocturnal species and female dominance and seasonal breeding in some diurnal species. One unifying trait possessed by most lemurs is the grooming claw on the second toe.

Lemuriformes are divided into five families including Daubentonidae, Cheirogaleidae, Lepilemuridae, Lemuridae, and Indridae. Of

these, it was Daubentoniidae, which includes the genus *Daubentonia* or aye-aye, that split off first at approximately 62–65 Mya (Yoder and Yang 2004), which is why it has posed some problems in terms of its placement in the Strepsirrhines (as described above).

Within the Daubentoniidae, there is only one genus, *Daubentonia* and one species, *Daubentonia madagascariensis*, which include the aye-ayes. Aye-ayes are small (2.3 kg), solitary, nocturnal primates that live in trees. They have elongated fingers and a compressed claw, that when used in conjunction with their long, curved incisors allow them to very effectively capture and feed on tree grubs from underneath tree bark. They also have a reduced dental formula of only 1.0.1.3, which includes rodent-like incisors that continually grow.

The five genera of the Cheirogaleidae (*Phaner*, *Cheirogaleus*, *Allocebus*, *Mirza*, and *Microcebus*) are the smallest of the lemurs with *Cheirogaleus* containing the dwarf and *Microcebus* the mouse lemurs weighing as little as 30 g. They subsist on a diet of mainly fruit and small prey including insects and small lizards. They are solitary and nocturnal and have enhanced hearing to assist with hunting during the night.

Lepilemuridae contains only the genus, *Lepilemur*, or sportive lemur. As the smallest folivorous primates, sportive lemurs weigh just under 1 kg and are around 0.5 m in length. In 2001, it was suggested that *Lepilemur* be combined with the extinct lemur *Megaladapis* in a family named Megaladapidae, largely based on similar dentition where upper incisors are not replaced by permanent dentition in adulthood. This, however, was later rejected, based on genetic evidence that revealed they were not close enough to each other to warrant being combined in one family (Wilson and Reeder 2005).

The family Lemuridae represents the lemur family with the most variation containing five genera including *Lemur* (ring tailed lemur), *Eulemur* (brown lemur), *Varecia* (ruffed lemur), *Hapalemur* (gentle lemur), and *Prolemur* (bamboo lemur). Unlike most other lemurs, these genera primarily move by slow quadrupedal

climbing and live in groups that are either diurnal (*Varecia*) or cathemeral. Their body size ranged from 700 g (*Hapalemur*) to 4.5 kg (*Varecia*) again showing much greater range than the other lemur families. Like with the variation in body size, there is also behavioral variation. Some species are diurnal, in opposition to the majority of Strepsirrhines that are nocturnal. This may be due to a lack of competition from monkeys on Madagascar enabling them to take advantage of the diurnal niche. In addition, some species of *Eulemur* and *Hapalemur* are cathemeral, which means that they are active throughout a 24-h period.

Indriidae includes three sister genera including *Indri* (Indriids), *Propithecus* (Sifakas), and *Avahi* (wooly lemurs). Of these, the Indri is the biggest lemur weighing up to 10 kg, whereas *Propithecus* and *Avahi* weigh substantially less at between 3.5 and 6.5 kg and up to 1.5 kg, respectively. They characteristically move by vertical clinging and leaping between trees or by jumping on the ground due to their long legs and tarsal bones that allow them to jump up to 30 feet. Generally herbivorous, Indriids eat primarily leaves although their diet may be supplemented with fruit and flowers. *Indriids* and *Propithecus* are diurnal, whereas *Avahi* retain the ancestral trait of nocturnality.

### Lorisiformes

Molecular studies, backed up with genetic evidence, suggest that lorises diverged from lemurs some 75 Mya. Currently, lorisiformes are distributed throughout mainland Africa and Asia and show much less variation than lemurs as all species are nocturnal and body size only reaches up to 1.5 kg. There is variation in movement patterns, with African species using slower quadrupedal climbing and Asian species relying on vertical clinging and leaping. Traditionally, lorisiformes are divided into two families: Lorisidae and galagidae; however, due to the monophyly of the lorisidae and a lack of genetic information on the galagidae, some have suggested it is more appropriate to classify them into subfamilies of lorisinae and galaginae.

The Lorisidae (lorises and pottos) are classified into six species in four genera (*Loris*, *Nycticebus*, *Arctocebus*, and *Perodicticus*). Lorises (*Loris* and *Nycticebus*) are distributed throughout Southeast Asia, whereas pottos (*Arctocebus* and *Perodicticus*) are distributed in Central Africa. Lorises and pottos are relatively small (85 g–1.5 kg), arboreal primates with specialized dentition. While they retain the lower tooth-comb, their anterior premolars are more canine than molar-like. They also have extended upper canines. Their postcranial skeleton is also different to other lorisiformes in that the wrist is modified to swinging in the trees and the forelimbs and hindlimbs are of equal length. They are all nocturnal and move slowly through the trees with quadrupedal climbing and avoid predation through cryptic behavior.

Galagidae include the galagos and bushbabies that are all distributed in Africa. It is currently thought there are five genera including: *Galagoides* (dwarf galagos), *Euoticus* (needle-clawed galagos), *Sciurocheirus* (squirrel galagos), *Otolemur* (greater galagos), and *Galago* (lesser galago) in this family. They are smaller and more gracile than the lorisidae and move by leaping through the trees rather than climbing. Unlike the lorisidae, males possess a baculum. Due to a lack of molecular and genetic studies, it is still uncertain if any of these genera are paraphyletic, which has cast doubt on this classification system. For example, there is evidence that *Galagoides* should in fact form two genera (*Galagoides* and *Paragalago*) (Masters et al. 2017).

## Haplorrhini

Haplorrhine primates include two infraorders: tarsiiiformes (tarsiers) and Simiiformes (monkeys, apes and humans; historically known as Anthroipoidea). Simiiformes are then broken down into two parvorders: Platyrrhini (New World monkeys) and Catarrhini (Old World monkeys, apes and humans). Haplorrhines have many distinguishing features from Strepsirrhines that include a flattening of the face that results from a decreased reliance on smell and an increased

reliance on vision. This is also the likely reason why Haplorrhines have dry noses and larger brains with more developed visual centers. Due to differences in diet, Haplorrhines also have different dentition and jaw morphology including fused lower jaws, shovel-like incisors, and the presence of a diastema between the upper lateral incisor and the upper canine tooth and larger, more generalized molars present near the back of the mouth.

## Tarsiiformes

As previously stated, tarsiiformes have a mix of traits associated with Strepsirrhines and Haplorrhines, which has made their taxonomic classification contentious. This has resulted in tarsiers being placed as either a sister taxon to the Strepsirrhines to form Prosimii or placed with the Anthroipoidea to form the Haplorrhines or as its own independent suborder altogether. Given their mix of behavioral and morphological traits (described below), it was not until genetic evidence showed that tarsiers are most likely to be part of the Haplorrhine lineage, that their taxonomy was resolved although they likely split from them nearly 90 Mya (Perleman et al. 2011). Tarsiers also maintain features that they do not share with any other primates including having the largest eye to head size ratio of any mammal, the ability to turn their head nearly 360 degrees, having two or three sets of nipples despite giving birth to single young, and having an unusually long tarsal bone (for which they get their name) that allows them to jump up to 20 feet in length. They are also the most carnivorous of the primates eating primarily insects and small vertebrates. They are currently found on the Islands of Borneo, Sulawesi, Sumatra, and the Philippines. Weighing in at between 80 and 160 g and measuring 85 and 165 mm, they are some of the smallest Haplorrhines. The infraorder contains only one family, Tarsiidae, and while previously thought to contain only the genus, *Tarsius*, it is now believed there are three genera of tarsier. These include *Carlito* (Philippine tarsier), *Cephalopachus* (western tarsier), and *Tarsius* (Eastern Tarsiers). Of these, the latter is thought to be the basal group that diverged first, while the two formers are believed to be sister taxa.

## Simiiformes

### Platyrrhini

The parvorder Platyrrhini includes the New World monkeys (or Neotropical monkeys) found in Central and South America. Like with the lemurs, there remains uncertainty surrounding the origin of the Platyrrhines and how they became distributed in the New World. Genetic studies using nuclear DNA have given variable dates of the divergence between platyrrhines and catarrhines, of between 33 and 70 Mya; studies based on mitochondrial DNA, however, give dates of separation between the parvorders of 35–43 Mya (Ciochon and Fleagle 1987). Regardless of the exact date, it also remains a mystery how this group of primates were able to cross the Atlantic Ocean and get from Africa to South America. It is thought this occurred in the Eocene, possibly through the use of a rafting event across the Atlantic Ocean. As it has been estimated that a small primate could survive up to 2 weeks on a vegetation raft, this is a plausible explanation due to the reduced distance separating Africa from South America at that time. Another hypothesis is that the animals “island hopped” by taking advantage of a lower sea level and the formation of Atlantic Ocean ridges. New World primates are distinguished from Old World primates by some physical characteristics including the positioning of the nostrils on the nose (platyrrhines have sideways oriented nostrils, while catarrhines have downward facing nostrils), body size (platyrrhines are smaller than catarrhines), and a difference in habitat use with all platyrrhines being arboreal. The lack of terrestrial platyrrhines may be due to limited grassland availability in South and Central America or the fact that the smaller body size of New World monkeys compared to Old World monkeys leaves them more vulnerable to terrestrial predators, meaning the arboreal environment may afford more protection from predation.

While initially platyrrhines were divided into just two families, the Callitrichidae that included any New World monkey that had claws and Cebidae that included everything else; this classification has since been rejected due to the fact this would have made Cebids paraphyletic. Currently,

it is agreed there are five families of monophyletic New World monkeys including Pitheciidae, Atelidae, Aotidae, Cebidae, and Callitrichidae. Of these, Pitheciidae diverged first followed by Atelidae and then Aotidae, Cebidae, and Callitrichidae.

Pitheciidae is a family made up of four genera and 40 species. Of these, *Callicebus* split off first followed by *Pithecia* then *Chiropotes* and *Cacajao*. While each of these genera have distinct physical appearances, they all share some features including dentition adapted to eating hard and protected fruit. They are also all found in the rainforests of South America where they move by slow quadrupedal climbing in the trees. Of the pitheciids, *Callicebus* are the smallest weighing up to 2 kg, while *Cacajao* are the largest weighing up to 3.5 kg.

Atelidae are the largest of the New World monkeys and the only group of primates to possess prehensile tails used for grasping. There are five genera within the Atelidae including *Alouatta* (howler monkeys), *Ateles* (Spider monkeys), *Brachyteles* (muriquis), *Lagothrix* (wooly monkeys), and *Oreonax* (yellow-tailed wooly monkeys). While *Oreonax* is commonly accepted as its own genus, this is not supported by genetic data (Rosenberger and Matthews 2008). Atelines are distributed throughout Central and South America with *Alouatta* being the most widely distributed (Mexico to Argentina) followed closely by *Ateles*. *Lagothrix*, on the other hand, are only found in the Amazon while *Brachyteles* are restricted to the Atlantic rainforest of Brazil and *Oreonax* are restricted to the cloud forests of the Peruvian Andes. Body weight among the genera ranges from 4 to 15 kg with the biggest being male *Brachyteles*. Unlike many other primates, some Ateline show male philopatry where males stay in the natal group and females disperse (Strier 1994).

Aotidae are referred to as the night monkeys as they are the only nocturnal monkey. There is only one genus, *Aotus*, that includes eight species. They are small monkeys weighing from 0.45 to 1.25 g and measuring 316–400 mm in length. Males and females of all species are generally the same size

and have the same appearance. All night monkeys are arboreal and share the same large eyes and flat, round faces. They are found throughout Central and South America with a distribution ranging from Panama to Bolivia, Argentina, and Paraguay; only *Alouatta* of the family Atelidae are more widely distributed in the New World.

Cebidae includes two subfamilies (Cebinae and Saimirinae). Cebinae include the capuchin monkeys and contains two genera *Cebus*, which include four species of gracile capuchin and *Sapajus*, which contains five species of robust capuchin. Until 2011, this subfamily only included *Cebus*, but genetic data revealed that there were in fact two groups that diverged from each other approximately 6 Mya, possibly due to the creation of the Amazon River that separated the two groups. In addition to genetic evidence, this split was supported by differences in morphology with gracile capuchins having longer limbs relative to body size and rounder skulls than robust capuchins that are better adapted to heavy chewing and a diet of nuts (Lynch-Alfaro et al. 2012). Robust capuchins also have crests and beards on the males. Capuchins are approximately 30–50-cm long with a tail of equal length. They are omnivorous eating a more diverse diet than other New World monkeys, they are also the most intelligent New World monkeys with the biggest brain to body size ratio of the infraorder. Capuchin monkeys range from Costa Rica down through South America as far south as Argentina.

The subfamily Saimirinae, the squirrel monkeys, contains five species in just one genus (*Saimiri*). Of the five species of Saimirinae, four live in the Amazon, with only one (*S. oerstedii*) found in Central America, Costa Rica and Panama. Until 1984, all squirrel monkeys were placed in the same species; however, this was rejected, and species are distinguished from each other based on the pattern of hair coloration around their eyes (Hershkovitz 1984). Squirrel monkeys measure 25–35 cm in body length with a tail that is at least as long as their body. Males and females are sexually dimorphic with males weighing approximately 0.75–1.1 kg while females weigh only 0.5–0.75 kg.

Callitrichidae includes six genera including *Saguinus* (tamarins), *Leontopithecus* (lion tamarins), *Callimico* (Goeldi's monkeys), *Callithrix* (Atlantic forest marmosets), *Callibella* (black-crowned dwarf marmoset), and *Mico* (Amazonian marmoset). While they were originally placed as a subfamily within Cebidae, this was rejected in 2005 (Wilson and Reeder 2005). They are the smallest of the Haplorrhine primates and unlike other monkeys have claws instead of nails. They also regularly give birth to twins and have a very high level of male parental care where males carry, feed, protect and play with infants in the group. They also show a unique social organization of cooperative polyandry, where only one female is reproductively active with subordinate females showing no ovarian cycling when in their natal group (French et al. 1984). This has been shown to be due to the physiological suppression of these females by the dominant, breeding female through pheromonal control (e.g., Puffer et al. 2004).

#### Catarrhini

Catarrhine primates include Old World monkeys, apes, and humans. As explained above, Catarrhine primates were separated from Platyrrhine primates somewhere between 33 and 70 Mya and can be physically distinguished by the placement of the nostrils on the nose. Catarrhines typically also have bigger body sizes than Platyrrhines and more diversity in habitat exploiting both arboreal and terrestrial niches. This parvorder includes two superfamilies, Cercopithecoidea (Old World monkeys) and Hominoidea (apes and humans).

#### Cercopithecoidea

Cercopithecoidea is a superfamily that contains only one family, Cercopithecidae, which includes all the Old World monkeys and is further broken down into two subfamilies, Cercopithecinae and Colobinae.

Cercopithecinae are the cheek pouched monkeys that are unified by the possession of cheek pouches used to store food. Many species also possess ischial callosities or “sitting pads” that change color in some species to signal sexual

receptivity. Thirteen genera are included in the Cercopithecines: *Allenopithecus* (Allen's swamp monkeys), *Miopithecus* (talapoin), *Cercopithecus* (guenons), *Erythrocebus* (patas monkeys), *Allochrocebus* (L'Hoest's monkey), *Chlorocebus* (vervets), *Macaca* (macaques), *Cercocebus* (collared mangabey), *Lophocebus* (crested mangabeys), *Mandrillus* (mandrills and drills), *Theropithecus* (Geladas), *Rungwecebus* (kipunji), and *Papio* (baboons). This subfamily is further divided into two sister tribes: Cercopithecini and Papionini. Cercopithecini includes the guenons, the patas monkey, vervets, and terrestrial guenons, Allen's swamp monkey, talapoin and arboreal guenons (*Cercopithecus*). Papionini then contains the other genera. Traditionally, there were only two genera in this tribe: *Papio* that contained the bigger species and *Cercocebus* that contained the more gracile ones. Genetic evidence refuted this, which was in fact supported by more detailed morphological studies that revealed there are in fact six genera in this group.

While both tribes exploit both arboreal and terrestrial habitats, most cercopithecine monkeys are limited in distribution to sub-Saharan Africa. This is except for *Macaca* that, aside from humans, have the widest distribution on the globe, ranging from Asia to Africa to Gibraltar. They also range from living in rain forests, savannahs, rocky mountainous areas, and snowy, high altitude locations. Within Cercopithecinae, the arboreal species are smaller and more gracile than the terrestrial ones. Despite differences in body size and habitat, the majority of cercopithecinae are omnivorous, diurnal, and live in large social groups.

Colobinae are the leaf-eating monkeys. They are unique among primates in that they rely on a diet very heavy in leaves that are high in indigestible fiber as well as secondary compounds. The presence of the secondary compounds (generally toxins and tannins) can render up to half of the protein in ingested leaves unusable, which when combined with the high fiber contents makes leaves a relatively low-quality food and hard to digest food item. Colobines have adapted to this, however, by evolving a suite of anatomical

specializations. These include the possession of enlarged salivary glands that produce copious amounts of saliva to help break down fiber before it reaches the stomach. In addition, it has been speculated that, like is seen in ruminants, their saliva includes tannin-binding properties to allow them to remove some tannins and increase the available protein of the food (Clausen 2003). They are also foregut fermenters, which also like ruminants, means that they have a multi-chambered forestomach where food is broken down and fermented (Langer 1988). The four chambers of the stomach are the saccus gastricus, the tubus gastricus, the pars pylorica, and the pyloric mucosa. They also have a large caecum and proximal (Kay et al. 1976; Chivers 1995) in which the presence of volatile fatty acids suggests that bacterial fermentation is also taking place (Kay et al. 1976). The stomach also generally has a pH between 6.5 and 8.0, below which an animal may suffer from acidosis.

While currently Colobinae are divided into two tribes, supported by geographic location and Mitochondrial DNA (Messier and Stewart 1997), there has been some contention around this as when using anatomical forestomach characteristics, it can be argued that the African Colobines may group more closely with some Asian colobines (*Semnopithecus*, *Trachypithecus*, and *Presbytis*), while the African procolobus better group with *Rhinopithecus*, *Pygathrix*, and *Nasalis*. That said, the current phylogeny supports Colobinae being divided into two tribes: Colobini that includes the African Colobines and Presbytini that includes the Asian colobines. The African colobines include the black and white colobus (genus *Colobus*), which is a sister genus to the other two genera of African Colobus: the olive colobus (genus *Procolobus*) and the red colobus (*Ptilocolobus*). The Asian colobines are made up of the odd-nosed monkeys (genera *Rhinopithecus* (snub-nosed monkeys), *Pygathrix* (doucs), *Nasalis* (Proboscis monkeys), and *Simias* (pig-tailed snub-nosed monkeys) as well as the *Semnopithecus* (Indian langurs), *Trachypithecus* (lutungs), and *Presbytis* (surilis). The Asian colobines inhabit a

wider range of habitats than their African counterparts as they live in moist, coniferous, and scrub forests as well as plantations in Indonesia and Malaysia and karst habitat in Southeast Asia. They also live in a wider geographic range from tropical lowland areas to high altitude and temperate montane zones.

#### Hominoidea

The superfamily Hominoidea contains the families Hylobatidae (small apes) and Hominidae (great apes and humans). It is distinguished from the other superfamily of catarrhine by lack of a tail, larger body size, bigger brain to body size ratio, and a slower life history pattern including longer gestation and a longer period of juvenile development. Hominoids also have a shorter spine relative to their body length, along with a broader pelvis that supports more upright posture and better balance than other catarrhines.

Hylobatidae are referred to as lesser apes or small apes and were originally divided into only two genera, *Symphalangus* (the siamang) and *Hylobates* (the gibbons). Due to an increase in genetic and vocalization data, however, there are currently four genera recognized, including: *Symphalangus* (one species of siamang), *Nomascus* (seven species of crested gibbons), *Hoolock* (three species of hoolock gibbons), and *Hylobates* (seven species of “44 chromosome” gibbons). It is believed that the four genera are sister genera that diverged from each other at approximately the same time; however, some mitochondrial DNA evidence suggests *Nomascus* was the first to diverge and *Hylobates* the most recently derived (Takacs et al. 2005). Hylobatidae are distinguished from Hominidae in that they are found only in the forests of Southeast Asia, where as Hominidae are distributed primarily in Africa, except for orangutans and humans. Hylobatidae are also distinguished from Hominidae by their smaller body size (3.9–12.7 kg), ischial callosities, and sexual monomorphism. In addition, they possess elongated forelimbs and shortened hind limbs, long curved fingers and toes, and reduced thumbs, all of which assist in brachiation, which is their primary mode of locomotion. They also live

in smaller social groups that are typically either pair bonded or a small social group of 2–6 individuals. They also tend to show the characteristic behavior of morning duet singing where the male and female in the group sing a unified song, which in some species is facilitated by the presence of a throat sac that acts as a resonating chamber to increase the volume of the vocalization.

Hominidae include the three genera of great apes *Gorilla* (gorillas), *Pongo* (orangutans), and *Pan* (chimpanzees and bonobos) as well as the one genus of humans (*Homo*). The taxonomy of great apes and humans has been heavily debated over the years. Initial classification systems saw all great apes placed together in their own family, Pongidae, with humans left as the only species in Hominidae (Sarich and Wilson 1967). While this was based primarily on morphological evidence, genetic studies have revealed that orangutans diverged first from the other hominids at 18 Mya (Hobolth et al. 2007) followed by gorillas at approximately 8–10 Mya (Sibley and Ahlquist 1984). It also shows that chimpanzees and bonobos are the most closely related species to humans, splitting at roughly 4–6 Mya (Hobolth et al. 2007). This warranted a new classification where all great apes were placed within the same family as humans (Hominidae) and then separated at the subfamily level with orangutans in Ponginae and gorillas, chimpanzees, bonobos, and humans in Homininae.

Hominids are much larger than their hylobatid counterparts weighing between 48 and 270 kg (male *Gorilla*). They also show sexual dimorphism with males being larger than females and typically live in larger social groups, although orangutans live solitary. They also show much longer developmental periods with orangutans not reaching sexual maturity until approximately 10–15 years and having an average interbirth interval of 7–8 years; this is much more than the 2–3 years common in many primate species. Movement patterns tend to be more upright with chimpanzees, bonobos, and gorillas moving by knuckle walking and orangutans moving by quadrupedal climbing. This has resulted in the great apes showing more robustness in their wrist bones than other primates to support a greater weight on

their forelimbs. Hominids also show much shorter forelimbs relative to their hind limbs compared to other primates.

## Conclusion

For the most part, recent phylogenetic assessments and classifications of primates have been done using molecular and genetic data. Thankfully, these have largely agreed with the more traditional classifications that were based on morphology. That said, disagreements do exist in some cases (i.e., the existence of *Oreonax* within the Atelidae and the arguments within galaginae). A bigger issue that has faced primate taxonomy and classification has come from the “lumping vs. splitting” debate. In this approach, lumpers tend to classify groups of taxa together unless there is a proven reason to split them into smaller and distinct groups. Splitters, on the other hand, tend to separate taxa into multiple groups unless there is a very good explanation not to. The argument against lumping is that it may obscure biologically important differences whereas the argument against splitting is that we end up with too many small and fragmented species groups. This has resulted in a varying number of primate species and subspecies being defined over the years, and at any one given time, different numbers of species and subspecies may be presented based on how the particular scientist decides to split or lump species. For example, in 2001, Colin (Groves 2001) split some species resulting in 350 primate species being defined in his seminal work *Primate Taxonomy*. This number was then further increased to 276 in 2005 in the *Mammal species of the world*. Due to recent research that has revealed new species and an increase in the use of genetic and molecular techniques, there are currently approximately 504 known primate species in the genera discussed here (Estrada et al. 2017).

Oligonucleotides; Oligos

## Definition

Primers are a short stretch of nucleotides acting as a starting point for DNA synthesis.

## Introduction

A primer is a short strand of nucleotide molecules (generally RNA or DNA of about 18–22 bases) which acts as an initial point for deoxyribonucleic acid (DNA) synthesis. These nucleotide sequences are specific and complementary to their target DNA sequences and allow selective amplification of that specific DNA sequence. Primers bind to denatured DNA template during polymerase chain reaction (PCR) by hybridizing to a complementary region of target DNA and provide a free 3' hydroxyl end. Further, a suitable heat-stable DNA polymerase in the presence of DNA precursors (the four deoxynucleoside triphosphates, dATPs, dCTPs, dGTPs, and dTTPs) initiates the synthesis of new DNA strands complementary to the individual target DNA strands at the 3' hydroxyl end. Similarly, an RNA primer serves as a starting point for DNA polymerase during DNA replication, while in vitro primers are short strand of chemically synthesized nucleotides for complementary DNA synthesis. The design of primers has a major impact on the success of PCR with respect to the specificity and yield of amplified product.

## Characteristics of a Good Primer

Primer designing is a crucial step for the success of PCR amplification. The characteristics of primers can help to evaluate the outcome of PCR experiment. The basic requirements for successful primer designing are considered as length of the primers, the primer length difference, the GC content, nucleotide composition at the 3' end of primer, melting temperature, and melting temperature difference of both the primers. Further, the secondary structures like dimers (including self-dimers and cross-dimers), hairpins, and specificity also affect the efficiency of PCR. The standard PCR primer design characteristics are as follows (Chuang et al. 2013):

1. **Primer length and primer length difference** – Primer length could be variable during PCR amplification. Generally, the optimal

length of primer pairs could vary between 16 and 28 nucleotides with a length difference of around three nucleotides.

2. **GC content** – GC content is a measure of the percentage of the ratio of total G and C nucleotides that appear in the primer. The appropriate GC content of a primer varies in the range of 40–60%. The variation in GC content may directly affect the annealing temperature. Therefore, checking the GC content of forward and reverse primer is a crucial step for PCR primer designing.
3. **Nucleotide composition at the 3' end of primer** – GC base pairing is thermodynamically more stable than AT base pairing. Enzymes selectively add bases to the 3' end of primed double-stranded DNA. Therefore, primers bind more tightly to the template DNA.
4. **Melting temperature** – The melting temperature ( $T_m$ ) is the most critical determinant to perform a successful PCR experiment.  $T_m$  of a primer pair varies between 50 °C and 62 °C. For successful PCR, the  $T_m$  difference of a primer pair should not exceed more than 5 °C. The ideal  $T_m$  difference of a primer pair is zero. The  $T_m$  of a primer could be calculated using mathematical formula given by Wallace, the Bolton and McCarthy, thermodynamic theory, or various other formulas (Wallace et al. 1979; Sambrook et al. 1989; You et al. 2008; Untergasser et al. 2007).
5. **Primer dimers** – The annealing between two primers during PCR results in primer dimer. The presence of dimer negatively affects the efficiency of a PCR. Thereby, hybridization of two primers should be avoided during PCR. Similarly, forward primer and the reverse primer may anneal to each other and may create cross-dimers or self-dimers when the forward primer anneals to another forward primer, or a reverse primer anneals to another reverse primer. Checking for dimers and primers self-complementarity is necessary to ensure the primer can hybridize with the template sequence and a crucial step for success of PCR.
6. **Primer hairpins** – A primer may anneal to itself and thereby it may form a secondary structure called as hairpin. Self-annealing of

primers should also be avoided. Forward and reverse primers should be individually checked for hairpins to allow for the specific hybridization of primers to the template sequence.

7. **Specificity** – Specificity is a crucial component of primer designing. A PCR experiment may be unsuccessful if the primers are not annealed to specific template regions or if they match to more than one position in the DNA template sequence. Therefore, it is important to determine whether a primer pair hybridizes to the target region or whether a primer matches with more than one position in the DNA template sequence or genomic sequence. The specificity ensures that the designed primer can detect a specific sequence to prevent invalid PCR results as well as for a successful PCR.

## Species of Primers

Traditional PCR primers are generally designed to anneal to specific target sequence and thereby act as primer for thermostable DNA-dependent polymerases. However, a wide variety of modified primers have now been developed which greatly broadened the scope of PCR applications (Pelt-Verkuil et al. 2008). These applications may be grouped into three categories:

1. 5' end modified primers
  2. Degenerate modification primers
  3. Miscellaneous primers
1. **5' end modified primers** – These primers are designed to be complementary to specific regions of target DNA sequence similar to traditional PCR but contain additional nucleotides at their 5' ends that are absent in target sequence. These additional 5' sequences are an integral part of the primers and amplify along with the rest of the amplified PCR products. These primers may require the use of lowered annealing temperatures during the first steps of the PCR cycling protocol. Examples of 5' end modified primers include:

- (a) **Restriction sites** – Restriction sites present at the 5' end of an amplified product facilitates cloning of the PCR product into a relevant vector. Different restriction sites could be designed into the 5' end of each of the PCR primer pair and thereby various PCR product cloning strategies could be developed. Further, some terminal nucleotides could be attached immediately upstream of the 5' end of the restriction site sequence for efficient recognition of the site by its restriction enzyme. These terminal nucleotides may be selected at random or adapted according to efficient optimal design of the PCR primer sequence like 50% GC content. These 5' end restriction sites should be chosen with precautions so that these restriction enzymes should not cut within the amplified PCR product itself.
  - (b) **Regulatory sequences** – PCR products could be transcribed into mRNA copies using DNA-dependent RNA polymerase enzymes at the 5' end promoter sequence. It allows the synthesis of a large amount of RNA which could be further used for several applications including RNA probes in hybridization studies and for in vitro protein synthesis studies. Bacteriophage T7 and SP6 promoters are the most frequently used promoters for in vitro RNA and protein synthesis.
  - (c) **Promoters and ribosomal binding sites (RBS)** – A functional 5' end promoter sequence could be designed in association with a ribosomal binding site, and an ATG start codon could be used for optimized in vitro coupled transcription and translation of PCR products. It allows mRNA and protein to be produced in a single “coupled” reaction system.
  - (d) **Capture haptens and fluorophores** – Using PCR protocol and its product, various sequence elements could be added to the 5' end of the primers. Thereby, homonucleotide stretches like poly-dT or poly-dA could be used for purification of the PCR product and RACE-like applications. The sequences of these primer pairs could also be labeled with various haptens such as biotin and digoxigenin as well as a wide variety of fluorophores like fluorescein. These primers labeling facilitates convenient immobilization of the PCR product on to the solid support through the interaction between PCR primer labeled with biotin and streptavidin bound paramagnetic beads and enables amplicon visualization. On the other hand, by attaching a specific monoclonal antibody to the fluorophores could help in the direct detection of the amplified PCR products.
  - (e) **GC clamp** – The 5' end of a primer could be increased by the addition of 20 or more GC bases. The addition of these GC sequence will alter the melting behavior and electrophoretic mobility of the final amplified PCR product. This primer is used for denaturing gradient gel electrophoresis.
2. **Degenerate modification primers** – Degenerate modification primers are designed to introduce target mutations into a specific piece of amplified DNA but are not fully complementary to their intended target sequence. For these purposes, they either do not contain one of the nucleotides of the target sequence or they may differ slightly in their primary sequence. However, these primers may result in incomplete hybridization at the target site which may create a hybrid structure involving bulging or looped-out nucleotides. These bulges or loops destabilize the hybrid structure which requires lowered PCR primer annealing temperatures, especially during the first few PCR cycles. Even more than one mutation located in the 5' half of a 20 nucleotide long primer could be amplified using degenerate PCR primers. However, if mutations are located at or near the 3' end of the primer, PCR amplification may be disrupted because 3' end binding of a PCR primer to its target is crucial in facilitating DNA polymerase mediated amplification. Therefore, degenerate sites should be located nearer to the 5' end of the PCR primer. To

amplify a target with high frequency of mutation, nucleotide inosine (which universally binds to G, C, A, and T nucleotides) could be incorporated into the primer design. Degenerate primers could be used for various PCR protocols, including

- (a) **Site directed mutagenesis** – Mutations present at 5' half of the primer will be found in the final amplified PCR product. Further, post-PCR manipulations, such as cloning/plasmid mediated transformation or transformation using the PCR product itself, allow the introduction and study of this mutated DNA in vivo.
- (b) **Degenerate oligonucleotide primer (DOP) PCR** – DOP PCR can be used to increase the amount of target DNA in a nonspecific manner. For this purpose, a large random mixture of primers is used in a PCR with as a net result the amplification of random genomic sequences. This approach could be useful for the general amplification of bacterial genomic DNA, extremely small amounts of DNA, and DNA from archival anthropological samples. DOP PCR can be combined with downstream methods also such as single nucleotide polymorphism (SNP) detection.
- (c) **Translating amino acid sequences into genomic sequences** – Degenerate primers could also be used to identify the gene sequence from which the original protein was translated and transcribed. These degenerate primers could be designed by using the amino- and carboxyl-terminal protein sequences and its reverse translation when the part of a protein sequence is known (e.g., after sequencing of a protein purified by classical chromatographic methods). Further, sequencing of the PCR products amplified using these pairs of primer will help to know the genomic sequence of the translated proteins.
- (d) **Universal primers** – Universal primers are also known as broad-range or consensus primers. These primers amplify similar target sequences in a variety of different subspecies of organisms. To design these

primers, a limited degree of degeneracy needs to be introduced into the PCR primers in order to account for all of the mutations found in the intended target sequence.

- (e) **Competitor primers** – These primers directly compete with one or more of the primers that have been designed to amplify the specific target DNA when added to the PCR mix. These primers contain dideoxynucleotide analogue at the 3' end and share part of the sequence of the amplifying primer pair. The addition of this dideoxynucleotide analogue effectively inhibits DNA polymerase-mediated replication of the complementary DNA strand to which the competing primer has annealed, and thereby could be useful in preventing the amplification of nonspecific products when PCR amplification is performed using extremely low amounts of target DNA. Competitor primers may also be used during the reverse transcription of mRNA to cDNA for highly specific quantitative RT-PCR protocols.
3. **Miscellaneous primers** – Miscellaneous primers could be used for various PCR protocols, including
- (a) **Repeat sequence primers** – The genomes of organisms consist of a higher percentage of DNA repeat sequence regions. These can be categorized into homopolymeric/heteropolymeric direct repeats, homopolymeric/heteropolymeric inverted repeats, composite heterogeneous repeats, or degenerate repeats and may be scattered throughout the entire genome of an organism. These DNA repetitive sequence regions may be targeted using single repeat sequence primers or multiple repeat sequence primer pairs. As sequence repeats alter with regard to genomic location and number between individual species and isolates, the number of successfully amplified PCR product fragments will differ. Further, this difference in amplified fragments will result in the production of specific DNA fingerprints for each species.

- (b) **Concatemeric primers** – These primers are used to generate a single large PCR amplification product by coupling overlapping PCR products altogether. For this purpose, the PCR protocol is designed to generate overlapping amplimers and the individual strands of these amplimers can partially hybridize. When these amplimers are melted into single strands and then reannealed, some of the amplimers hybridize to each other and act as primers for DNA polymerase. This will lead to the generation of a new and longer DNA product. This concatemer PCR approach has been very important in amplifying significantly large-sized fragments of DNA from and samples that have been subjected to violent extraction protocols resulting in highly sheared and fragmented DNA.
- (c) **Multiplex PCR primers** – Multiplex PCR protocols involve the addition of up to ten different PCR primer pairs within the same PCR reaction mix but they do not overlap like concatemer primers. In order to facilitate this, multiplex PCR normally contains primers which are somewhat extended (28 nucleotides instead of the more customary 18–22 nucleotides) to enhance primer specificity and help prevent unwanted primer/primer annealing interactions.
- (d) **Megaprimers** – Megaprimers consist of primers of around 450–800 bp long which could be used in mutagenesis protocols. After initial hybridization at 37 °C, a limited number of PCR cycles ( $n = 7$ ) are performed and the megaprimers are extended from the 3' end outwards. After limited PCR cycling, a normal PCR protocol is performed using this amplified product from the megaprimer PCR and another pair of specifically designed normal length PCR primers for selective amplification. These normal PCR primers could also be associated with additional site-directed mutations.
- (e) **Molecular beacons** – Molecular beacons are a primer or probe that contains a self-

complementary sequence and forms a hairpin-like secondary structure. This hairpin structure contains a fluorescent reporter molecule and a quencher molecule closely together in the region of folding. If the reporter and quencher molecules are in close proximity, reporter molecule does not give the fluorescence. However, once the molecular beacon primer is incorporated into amplified DNA product during the first PCR cycle, the reporter group and its quencher become separated and reporter molecule gives the fluorescence upon excitation and is recorded with the progress of PCR.

Canada

### Definition

The presentation of an idea or information that can alter subsequent behavior.

### Introduction

Priming is the presentation of an idea or information that can alter subsequent behavior. It may be presented in the form of a word, image, sound, or a more complex task. For example, presenting a word very briefly may make people faster at responding to that word or a related one in a subsequent task. Priming is an example of implicit memory and does not involve conscious recollection of any previous experience (Tulving and Schacter 1990). Its effects often occur unconsciously, without the observer's knowledge. Priming effects can be short-lived or long-lived (up to 48 weeks; Cave 1997) depending on the nature of the stimuli and tasks used (Bentin and Moscovitch 1988). Priming typically functions both within and across sensory modalities, with the exception of perceptual priming which depends on modality-specific features.

### Types of Priming

Priming can be broken down into many categories depending on the perceptibility of the prime, the nature of the prime and target, the task instructions, and the effect it has on the target stimulus. For instance, priming can impact perception, word choice, speech structure, or preferences, and people may be aware or unaware of the prime they are perceiving. Different types of priming also recruit different neural regions based on the demands of the task.

### Positive and Negative Priming

Primes can be separated into positive and negative primes. Positive primes are those that help a participant's task performance by speeding reaction times and improving accuracy. They do so by priming a word or idea that is the same or related to the target in some way. Negative primes, on the other hand, hinder performance by slowing reaction times and lowering accuracy. Negative priming occurs when the prime is ignored rather than simply perceived.

### Supraliminal and Subliminal Priming

A prime may be presented either supraliminally or subliminally. Supraliminal presentation means the prime is presented at a speed and contrast that can be consciously perceived by the observer, even if they do not realize the impact it produces on their subsequent behavior. A subliminal prime, on the other hand, is one that is presented such that it cannot be perceived by the observer. This may be done using very quick presentation times (less than 500 ms and often only tens of milliseconds) and masking. Masking is the use of symbols immediately after the prime and in the same location, which make it more difficult to perceive by eliminating any afterimage. A mask can also be included immediately before the prime word is presented (e.g., Dehaene et al. 1998).

### Perceptual and Conceptual Priming

Perceptual priming is modality-specific and dependent on the physical features of the prime and target stimuli, while conceptual priming is dependent on the meanings and semantic features of these stimuli (Roediger III and McDermott 1993). Perceptual priming can be demonstrated by the ability to identify the target word more quickly, to perceive words that have been degraded, or to perceive perceptually similar words (e.g., goat and boat). Conceptual priming is demonstrated through tasks that require identifying semantic features. These types of priming can be directly compared by changing the task instructions. For example, participants may be asked to indicate whether a string of characters is written in uppercase or lowercase letters, which would promote perceptual priming, or whether the

word is an object that moves, which would promote conceptual priming. Semantic priming involves priming stimuli with related meanings (e.g., the word “dog” priming the word “wolf”) and may be produced by activation spreading through semantic networks (Collins and Loftus 1975) or through changes in attention (Posner and Snyder 1975). Associative priming involves stimuli that are commonly present in the same contexts (e.g., the word “cat” priming the word “mouse”).

### Structural Priming

Studies have also demonstrated priming of syntactic structure. People read a written clause more quickly if it has a similar syntactic structure to a previously read clause (Elgendi et al. 2018). They are also more likely to use the primed structure in subsequent speech, even in a different language (Loebell and Bock 2003).

### Affective Priming

In addition to behavior on perceptual or language tasks, priming has been shown to affect people’s attitudes toward subsequent objects or stimuli. For example, Murphy and Zajonc (1993) demonstrated that emotional expressions presented through subliminal priming were able to produce more positive or negative judgments toward neutral Chinese ideographs. Similarly, Greenwald et al. (1996) biased participants’ judgments regarding target words based on the positive or negative valence of the prime word.

### Priming Cultures and Social Categories

Not only can priming affect how people perceive objects and stimuli; it can also influence how they perceive those around them and even themselves. For example, Herr (1986) demonstrated that participants described ambiguous target individuals differently based on primed social categories. Priming is thought to play an important role in stereotyping, because trait descriptions of individuals or groups will prime those ideas as interpretations of behavior later on. Furthermore, there is evidence that activation of a specific cultural mindset through priming affects the way individuals behave. For example, some cultures are

perceived as more individualistic, meaning people are perceived as independent and autonomous and the needs and goals of the individual are emphasized more than those of the group. Other cultures are perceived as more collectivistic, meaning they value the needs of the group or community over those of each individual. Many people identify with more than one culture and therefore acquire both individualistic and collectivistic views, which may each be activated depending on the situation. Priming a certain mindset may change the way an individual thinks and behaves toward others, as well as their neural activity (e.g., Knyazev et al. 2018). This demonstrates that cultural priming can lead individuals to perceive themselves and their goals differently and therefore select different behaviors.

### Common Priming Tasks

Some commonly used priming tasks include repetition priming, word-stem completion, and lexical decision tasks. Repetition priming is a common form of priming that simply involves changing a participant’s ability to identify a word or object by showing it beforehand. Repetition priming may be done either supraliminally or subliminally and within or across many sensory modalities. Identification of target words is faster (Dehaene et al. 2001) and more accurate (Bar and Biederman 1998) when they were previously shown as primes compared to when they are first shown. This has also been demonstrated using masked subliminal priming (Dehaene et al. 1998). Word-stem completion involves filling in the remainder of a word based on an initial morpheme that is provided. If participants are provided with a word bank before the task, they are more likely to use these words, compared to if they did not see any word options previously. The lexical decision task is a semantic priming task that involves determining as quickly as possible whether a string of letters is a word or not. Participants are consistently faster at doing so if the trial is preceded by a related prime word. For example, the prime word “doctor” would produce faster responses indicating that the target word “nurse”

is a word, compared to if “nurse” was shown with no prime or an irrelevant prime word.

## Neural Responses Associated with Priming

Many studies have attempted to delineate the neural responses associated with priming effects. A general conclusion is that repeated presentation of stimuli through priming experiments produces a reduction in neural activation (e.g., Schacter and Buckner 1998), which is interpreted as more efficient stimulus processing. The regions exhibiting this reduction vary depending on the type of priming used. A suppression of occipitotemporal areas has occurred in response to priming in word completion tasks (Henson 2003). This has been shown in both visual and auditory modalities but only in unimodal paradigms. A reduction is not typically shown in the early sensory regions or motor areas, demonstrating that not all components of the stimulus processing are altered; however there is some evidence of changes in motor areas in response to masked subliminal priming (Dehaene et al. 1998). Repetition suppression in the left angular gyrus may indicate lexical priming, while in the left inferior frontal regions it likely indicates repeated conceptual processing of words (Poldrack et al. 1998) or reduced competition between possible responses (Thompson-Schill et al. 1999). Several studies have shown an increase in right frontal lobe activation on primed trials, which is thought to indicate an accidental encoding of the stimuli into explicit memory (Badgaiyan et al. 2001). The effect of masked subliminal priming on neural activity is not completely evident, and some researchers have even found enhancement effects rather than suppression (e.g., Schnyer et al. 2002).

## Priming in People with Brain Damage, Alzheimer’s Disease, and Huntington’s Disease

Priming effects occur even without explicit recall of the prime. This can be demonstrated by the presence of priming effects even in people with brain damage to temporal regions that impairs explicit memory (e.g., Warrington and Weiskrantz

1974). However, most of these studies have used perceptual priming techniques, and the results are less clear for conceptual priming. Alzheimer’s patients are more impaired in conceptual priming but show fairly intact perceptual priming effects. Finally, intact perceptual priming has been demonstrated in people with Huntington’s disease (Salmon and Butters 1995), demonstrating that motor learning and priming likely depend on different brain systems.

## Applications of Priming

Priming has implications for everyday human behavior, such as in the cases of advertising, human-computer interactions, and political campaigns (Elgendi et al. 2018). For example, children automatically consumed more food when they were shown food advertising during a television show (Harris et al. 2009), compared to advertising of other items. To facilitate human-computer interactions, priming can be used to enhance certain ideas for the person to increase comprehension. In politics, more positive ideas can be primed in voters through a focus of the media on certain issues. Even in the absence of intentional priming, individuals are constantly perceiving stimuli around them, each of which has an impact on how they behave. However, by being aware of the impact of their surroundings, people can try to select environments that prime positive goal-directed behaviors while avoiding those that prime negative behaviors.

## Doubts Regarding Priming Effects

Despite its long-standing presence in the field of psychology, priming has been criticized as a topic that is especially susceptible to the expectations of experimenters, as well as publication bias. These factors may produce bias in the priming literature that result in an inflated certainty in the robustness of these effects. This doubt has caused many people to worry about the validity of priming studies. One high-profile example of this is a pioneering experiment by Bargh et al. (1996).

The study concluded that university students exposed to words describing elderly people (e.g., wrinkles, Florida) walked more slowly down the hallway following the experiment. A replication attempt used infrared sensors instead of experimenters with stopwatches to time the walking speed and found no difference in the walking speed (Doyen et al. 2012). This study and others have led priming research to become the “poster child for doubts about the integrity of psychological research,” according to psychologist and Nobel Laureate Daniel Kahneman. An increased effort to replicate findings both within and across psychology labs is necessary to confirm these findings and determine confounding variables in priming research.

## Conclusion

Priming is a commonly used method in psychological research for studying implicit memory. Priming may be done through conscious or unconscious means and can affect perception, attitudes, and behaviors. Priming effects have been shown within several different sensory modalities as well as in cross-modal paradigms; however, further replication is needed to confirm the validity of many priming experiments. Priming has real-world effects including determining susceptibility to advertising, improving human-computer interaction, and understanding the influence of ideas used in political campaigns. The objects, words, and concepts that we deal with each day have an influence on our subsequent behavior, and understanding the effects of priming is an important step toward understanding that influence.

## Overview

Game theory is a set of ideas developed with the goal of applying analytical rigor to understand decision-making. It includes consideration of key aspects that affect a decision, such as the nature of possible outcomes and the associated incentives (e.g., various degrees of payoff or punishment associated with outcome A versus outcome B). One of the most interesting aspects of game theory is that multiple participants are involved. Each participant can only make their individual choice, but the nature of the global outcome depends on both of their choices. In that way, each participant plays a role in shaping the global outcome, but neither has exclusive control over what happens. Each participant is assumed to be rational and acting in their own best interest, yet an outcome can sometimes emerge in which neither player achieves their optimal outcome. Thus, each participant chooses what is best for them, but that may not always yield the outcome that is best for the group. One of the most well-known ways in which this concept has been framed is the Prisoner's Dilemma in which two prisoners accused of the same crime are interrogated separately and asked whether or not they will confess to the crime. There are costs and benefits associated with their possible choices, and experts have used that scenario as a way to investigate the logical basis of decision-making. Specifically, how do individuals make decisions when risk and reward are involved, and what happens when the outcome that is best for the group is not what is best for each individual? In the following sections, we describe the history and concepts of the Prisoner's Dilemma, and we

discuss ways in which ideas emerging from that analysis have been adopted by organizations such as companies and nations seeking to benefit in their interactions with partners and competitors.

## Historical Background

The foundations of game theory include an assumption of rationality (Davis 1983; Leyton-Brown and Shoham 2008; Myerson 1991). Players in games are assumed to act rationally, meaning that they are expected to choose their actions based on logic and reasoning (Rapoport 1992; Skyrms 1990). This ideal has had to be adapted in the course of research into how mathematical models may account for human behavior, as the behavior of humans and other organisms can be very difficult to characterize and often deviates from a single ideal outcome (Glimcher et al. 2009; Thaler and Sunstein 2008). This is because different choices can each be considered rational despite the fact that they result in very different outcomes. For example, consider a case in which each of the members of a group is dependent on a shared resource in order to survive. If we consider the well-being of the group, we would expect that each member would act in such a way that they would not only benefit from the resource but also preserve it for continued shared use in the future. However, if we consider the well-being of each individual separately, we would expect each member to want to take more for themselves even though that would come at the expense of the group. In each of these possibilities, the members of the group are making rational choices, but the difference lies in whether they are focused on the well-being of the group or themselves as individuals. In this scenario, each individual is incentivized to make choices in a way that is less than optimal for the group. Each individual seeks to protect themselves at the expense of the others, and as a result both end up in a state that is worse than if they had worked together to coordinate their decision-making.

This paradox of decision-making is one of the most well-known ideas associated with game theory, and it lies at the heart of the Prisoner's

Dilemma. These differences between expected and observed behaviors have intrigued experts in economics, psychology, and policymaking, and those researchers have sought to formalize their thinking about that process. In the first consideration of this process, researchers Merrill Flood and Melvin Dresher at the RAND Corporation envisioned a "game" in which two individuals each contributed to choosing an outcome that would affect them both (Flood 1958). Each player was faced with deciding what decision-making process would be best for them individually when the consequences were predictable but the behavior of the other player was not. This challenge of how to make the best decision in a mutually dependent outcome is the essence of what eventually came to be known as the Prisoner's Dilemma, but it awaited contributions from others before it was framed in the way that we consider it today.

## Developing a Formalized Understanding of the Prisoner's Dilemma

When Flood and Dresher first proposed their hypothetical scenario, they and others quickly realized that it is an excellent example of challenges faced by participants in many forms of interaction, from board games to economics to international policymaking. A fundamental advance in the thinking about these scenarios occurred when Princeton mathematician Albert Tucker proposed the context of two people who were each accused of the same crime (Tucker 1950) (Fig. 1). Each person was seeking to minimize their punishment and maximize their benefit, but cooperation was not possible because each was being interrogated separately. In that scenario, each prisoner was told that:

- (1) If one confesses and the other does not, the former will be given a reward of one unit (+1 in the value of the outcome) and the latter will be fined two units (−2 in the value of the outcome).
- (2) If both confess, each will receive a lesser fine (−1 in the value of the outcome for each).

|            |             | Prisoner B  |         |
|------------|-------------|-------------|---------|
|            |             | Not Confess | Confess |
| Prisoner A | Not Confess | 0, 0        | -2, +1  |
|            | Confess     | +1, -2      | -1, -1  |

**Prisoner's Dilemma, Fig. 1** The benefits (positive numbers), punishments (negative numbers), and possibility of going free (zero values) inherent in the decisions faced by each participant in the Prisoner's Dilemma

At the same time, each prisoner has good reason to believe that:

- (3) If neither confesses, both will go free (0 value of the outcome for each).

In subsequent considerations of this scenario, it was further stipulated that both prisoners fully understand the nature of their choices and the associated consequences, neither prisoner has an opportunity for retribution or reward outside of the game, and neither prisoner has any loyalty to the other (Poundstone 1992). In other words, each prisoner acts in their own self-interest and makes their decision independently of the other.

In this scenario, the overall most beneficial result would occur if both players choose to not confess, as both would go free and neither would be fined. Thus, choosing to not confess could yield freedom, but it also exposes each decision-maker to the greatest possible risk if the other prisoner confesses. Therein lies the dilemma – should the prisoner choose the option that could enable them to achieve the best global benefit or the option that could enable them to avoid the worst individual punishment? Should they act in the best interest of the group or of themselves? If the prisoners were able to coordinate their strategies and form a cooperative solution, the safest

and most beneficial option would be for them to each choose to not confess. However, in Tucker's scenario, the participants are not able to work together and form such a coalition. Therefore, each participant lacks the assurance associated with coordinated decision-making.

In the absence of coordinated assurance and collective action, each participant is incentivized to act in their own self-interest. In the case of the prisoners in this scenario, each is incentivized to confess, making confession the dominant strategy for both players. This dominance emerges because neither player is able to improve their individual payoff by altering their strategy (Rapoport 1992). For example, if Player A chooses to confess, Player B is better served to confess (−1 outcome) than to not confess (−2 outcome). Similarly, if Player A chooses to not confess, Player B is still better served to confess (+1 outcome) than to not confess (0 outcome). Regardless of what the other player does, confessing always results in the better payoff. An action profile such as this, where no single player can increase their payoff by deviating from their initial strategy while the other player remains unchanged, is known as Nash equilibrium (Nash 1950). Princeton mathematician John Nash recognized and described this pattern of making choices in the face of uncertainty, and the Nash equilibrium is considered the most rational outcome. In the scenario involving Players A and B, the Nash equilibrium is mutual confession (the bottom-right quadrant in Fig. 1). It results in a small fine, but it also enables them to ensure that they avoid the possibility of a much larger fine. Even though mutual cooperation (both choosing to not confess) would yield the best outcome for both, two players seeking to maximize their own payoff and minimize their own risk would be expected to choose the Nash equilibrium of mutual confession.

The rewards and punishments that drive the emergence of this behavior can be even more easily observed when the game is removed from the familiar context of prisoners and confessions to a more general context in which there are two players with the two options of “cooperate” or “defect” (Fig. 2). If Player A and Player B both

|          |           | Player B             |                          |
|----------|-----------|----------------------|--------------------------|
|          |           | Cooperate            | Defect                   |
| Player A | Cooperate | Reward<br>Reward     | Sucker<br>Temptation     |
|          | Defect    | Temptation<br>Sucker | Punishment<br>Punishment |

**Prisoner's Dilemma, Fig. 2** – The rewards and punishments associated with each player's decision in a generalized form of the Prisoner's Dilemma (adapted from Fig. 1 in Axelrod and Hamilton 1981)

cooperate, they will each receive the “reward” payoff (R). If they both defect, they will each receive the “punishment” payoff (P). If either player is the sole defector, they will receive the “temptation” payoff (T), while the other player who chose to cooperate when their opponent chose to defect will receive “sucker’s” payoff (S). The magnitudes of the rewards or punishments may vary in different scenarios, but a condition like the Prisoner's Dilemma emerges when participants are asked to each engage in an independent choice and the relationships among those outcomes satisfy the condition that  $T > R > P > S$  (Axelrod and Hamilton 1981; Poundstone 1992; Rapoport et al. 1965).

### Iterated Prisoner's Dilemma and the Emergence of Strategies

In the original vision of the Prisoner's Dilemma, the game was only played once (Poundstone 1992). In that context, each player must make their decision based only on the set of actions available to them and the payoffs or consequences associated with each action. Each player must seek the most beneficial outcome even in the face of a completely unknown choice to be made by the other player. This scenario has led to the

emergence of insights about how to make rational decisions in the face of uncertainty, but it fails to allow for the possibility that interactions and the associated choices may occur more than once. When the game is played more than once, players can learn from the previous actions of their opponent and modify their own strategy accordingly. Therefore, the factors influencing each player's decision are not only the payoffs for each action but also their experience and knowledge of their opponent's past behavior as well as their intuition about their opponent's future behavior. This scenario in which each player makes a choice but repeated interactions are possible is referred to as the iterated form of the Prisoner's Dilemma (Poundstone 1992). When the game is played more than once, risks and rewards must be weighed not only in the immediate next step but also in light of past experiences and possible future interactions.

The opportunity for each player to learn from experience and modify their behavior during repeated interactions gives rise to the possibility that each player may develop different types of strategy (Axelrod and Hamilton 1981). In the relatively simple game envisioned in the Prisoner's Dilemma (Fig. 2), both players have two possible actions: they can either cooperate or defect. Strategies can be broadly categorized as those that begin with cooperation (the so-called “nice” strategies) and those that begin with defection (“mean” strategies). When both players are nice, both get an immediate reward. If both players are mean, both players receive the punishment result. The incentive is greatest for a player to be mean when their opponent is nice (temptation payoff goes to the mean player, and the nice player receives the sucker's payoff). The names for each of these strategies reflect the outcome associated with the first choice that each player makes, but much more complex strategies can emerge when we consider how those outcomes may affect subsequent choices.

A player may change their responses based on the opponent's previous actions (a reactionary strategy). For example, a player may change away from cooperation only after their opponent

chooses to defect for the first time. If that player remains in defection, it can be called a “Friedman” or “grudger” strategy because the player’s behavior changed once in response to a mean action and remained fixed thereafter (Axelrod 1980a). Alternatively, a strategy may include an element of “forgiveness” in which behavior may continue to remain variable even after the opponent engages in a mean action. If short-term history dependence is incorporated into that strategy, then a “tit for tat” strategy can emerge in which a player changes their behavior to match that of the previous action made by the other player (Axelrod 1980a). In other forms of strategy, a player may change their response based on some inherent feature of that strategy in which changes are made preemptively in an attempt to gain advantage or to test the reaction of the opponent (a preemptive or testing strategy). For example, if a player detects that their opponent very regularly chooses to cooperate, then the best choice for that player would be to defect, as the player would receive the temptation payoff and the opponent would be stuck with the sucker’s payoff. These types of contingent or preemptive strategies seek to probe the patterns of responses expressed by their opponent and to use that information to exploit other simple strategies to gain advantage.

In seeking to understand which strategies may be most beneficial when games are played more than once, researchers created different kinds of strategies and tested their effectiveness when pitted against one another in simulated competitions. In 1979, a researcher named Robert Axelrod held a simulated tournament in which 14 different types of iterated Prisoner’s Dilemma strategies, as well as 1 random strategy, competed in an attempt to determine which types of strategies were most broadly beneficial (Axelrod 1980a, 1984). In this competition, the iterated version of the Prisoner’s Dilemma still included two possible actions for each player. Those actions were still called “cooperate” and “defect,” but the associated outcomes were considered in the context of earning points rather than avoiding a prison sentence (Axelrod 1980a). If both players defected, then they each gained a small amount of points. On the other hand, if both

players cooperated, both gained a significantly greater amount of points. If one player defected when the opponent cooperated, then the defector received the maximum amount of points, and the player that cooperated received zero points. The value of any strategy relative to others is ultimately dependent on the magnitudes of those point values in the payoff matrix, but this arrangement of  $\text{temptation} > \text{reward} > \text{punishment} > \text{sucker's payoff}$  is the same as described for the generalized form of the Prisoner’s Dilemma.

In Axelrod’s tournament, strategies that began with cooperation (“nice” strategies) tended to fare better than the “mean” strategies that began with defection (Axelrod 1980a). The winning strategy in that competition was the “tit for tat” strategy, created and entered by Anatol Rapoport, in which the player cooperates in the first round and then in each subsequent round simply mimics what the opponent selected in each previous round (Kopelman 2020). In this way, the opponent receives the treatment that they gave in the immediately preceding round, hence the name tit for tat. This strategy is one in which the player retaliates when provoked but otherwise cooperates. The success of this strategy against a wide variety of opponents suggests that there is an advantage in not only behavioral flexibility but also adaptation in the patterning of those behaviors. A similar tournament followed up on that first tournament, this time with an even greater variety of 62 different strategies and 1 random strategy pitted against one another (Axelrod 1980b). Despite the greater variety of opponents, tit for tat again emerged as a broadly beneficial basic strategy. Although tit for tat is not always the overall winner in these types of tournaments, it tends to fare very well across repeated interactions with many different types of strategies, further confirming the value of behavioral flexibility and history-dependent adaptation. A topic of ongoing research is the degree to which different depths of history dependence may be beneficial. For example, what if a player alters their strategy based on not only the previous action of the opponent but also the nature of the collective outcome that it produced (the so-called “win-stay, lose-switch” strategy) (Imhof et al.

2007; Nowak and Sigmund 1993)? What if a player alters their behavior based on not only the most recent action by an opponent but also in response to other actions from the more distant past? In that light, researchers are exploring the degree to which it may be beneficial for strategic algorithms to be “forgetful,” such that only the most recent events matter, or to have some sort of “memory”, in which actions from the more distant past are influential in driving current actions.

### **Relevance of the Insights from the Prisoner's Dilemma for Real-World Applications**

The scenarios and outcomes illustrated by the many forms of the Prisoner's Dilemma reveal the intricacies of decision-making that can arise in those fascinating contexts, but they leave open the question of how insights from the Prisoner's Dilemma may be applicable to decision-making in more practical terms. There are many types of interactions in nature and human society in which choices and consequences can be described using a payoff matrix very similar to those found in the Prisoner's Dilemma (Axelrod and Hamilton 1981). In that way, the choices that participants must make in those contexts can be modeled as a form of the Prisoner's Dilemma, and insights from those scenarios can be applied to develop a better understanding of ourselves and processes in the world around us.

The iterated Prisoner's Dilemma has been used to model interactions in which trust between two participants is essential for their collective success. In the variation known as Rousseau's Stag Hunt, the familiar context of the Prisoner's Dilemma is modified such that the participants are two hunters (Skyrms 2004). Each hunter can pursue either stag or rabbit. The stag would provide a large meal that could feed all of the members of their group, but it is very challenging to hunt and requires the cooperation of both hunters in order to collect it. In contrast, a rabbit is a much smaller meal, sufficient to feed only the hunter, and is much easier to catch, requiring only one

person to collect it. In this scenario, the greater reward of catching a stag requires the cooperative efforts of both hunters, and their success is uncertain. A hunter who chooses to pursue stag runs the risk of their partner choosing to not cooperate, and such a result would leave them with no food. A hunter who chooses to pursue rabbit has a much greater chance of meeting their own needs, but that reduction of risk means that they necessarily forgo the chance to collect the greater reward. The dilemma in this scenario emerges when rational players are drawn toward one option by the possibility of mutual benefit but are pulled towards the other option by the prospect of avoiding individual risk (Skyrms 2004). The most beneficial choice for the group would be to hunt stag, but that cooperative benefit would require cooperative action, and that would require each hunter to trust their partner. In that way, Rousseau's Stag Hunt models situations in which cooperation is difficult but still possible to achieve. Cooperation emerges through communication and experience as a form of social contract that is contingent on each person's belief about what the other person will do. With the accumulation of experience and the development of trust, it becomes more likely that each player can predict the behavior of the other, and they become more comfortable choosing the relatively risky option of cooperation. Thus, insights from the Prisoner's Dilemma reveal how accumulation of knowledge can provide benefits through not only prevailing in adversarial situations but also gradually learning how to work together in cooperative situations (Axelrod and Hamilton 1981; Axelrod 1984; Axelrod and Dion 1988).

The Prisoner's Dilemma can also be used to model the behavior of nations engaged in competition for superiority and security (Jervis 1978). For example, a nation that arms itself is prepared to prevail over an opponent or deter that opponent from attacking, but building those armaments comes at the cost of resources and time. Choosing to disarm would save costs, but that would also make that nation vulnerable to attack. Mutual development of arms by two nations could provide an effective deterrent of conflict, but both

groups would encounter the costs of developing those weapons. Mutual disarmament would reduce the threat that each nation poses to the other, and it would also provide the additional benefit of reducing costs. As in the scenario of the two hunters that were dependent on one another for their well-being, trust is the central factor in this scenario. The least costly outcome would be mutual disarmament, but that would require trust of not only the other nation but also of other nations that may also be able to affect their well-being. Just as it was for the hunters, trust is a rare and precious commodity in any interaction between participants. Lack of trust makes self-interested behavior the only rational choice, and those types of interactions are evident in the relationships between many nations and other groups.

It is tempting to apply the lessons of the Prisoner's Dilemma across a wide range of practical scenarios to devise ways to incentivize specific behaviors or develop ways for participants to resolve conflict and perhaps even cooperate (Rapoport 1962). However, a fundamental challenge to such attempts often lies in the nature of the payoff matrix. In the Prisoner's Dilemma, the rewards or punishments associated with each choice are clear – if the prisoner chooses to cooperate, then there are only two actions that can possibly be performed by the other participant, and only one of two clearly defined outcomes can emerge. In the context of many attempts to apply the Prisoner's Dilemma to practical scenarios, those potential outcomes are not fully known and thus not possible to clearly define. In this way, not all scenarios are amenable to analysis through direct application of the Prisoner's Dilemma, especially those in which there is significant uncertainty regarding possible outcomes.

As evident in the scenario of the Stag Hunt, making rational choices based on the greater good requires trust between participants. This challenge is especially evident in the context of global climate change. As rising levels of atmospheric carbon dioxide appear to be driving correlated changes in climate, those changes are causing instability and undesired events that will continue

if they are not countered by initiatives meant to reduce levels of CO<sub>2</sub> in the atmosphere (Raper and Braithwaite 2006; Solomon et al. 2009). All nations would benefit from reduced levels of CO<sub>2</sub>, but the changes necessary to cause those reductions may be very challenging and costly (Reid et al. 2010). Therefore, each nation is simultaneously incentivized to maintain current behavior or otherwise avoid the expense associated with changing emission behaviors. If trust could be forged between two nations, then they could cooperate in their approach to this challenge, but without trust among all participants, those two cooperators would still be subject to defection and the sucker's payoff if other nations did not join them in their efforts. This challenge further illustrates how valuable trust between participants can be as a means of enabling coordinated action and rational choices that lead to the most broadly beneficial outcomes.

In many real-world scenarios such as each nation's decision of how to take action in response to climate change, there are many more than just two players. The challenge of finding ways to act in the best interest of the group becomes even greater as more players become involved. These types of scenarios in which many individuals share a resource and act independently in their own self-interest are sometimes called the Tragedy of the Commons (Hardin 1968). In those cases, individual users of a resource are incentivized to act in their own interest, but this comes at the expense of the common good. Through their actions, each user experiences short-term benefits, but the resource is adversely affected through their collective actions. Cases such as this in which there are many individual participants all incentivized to act in their own self-interest are especially difficult to analyze and even more difficult to devise solutions that lead to sustainable group well-being. Despite the scale of these daunting challenges, researchers continue to use the ideas inherent in the Prisoner's Dilemma as a context in which to seek generalizable insights into how the members of a population may achieve cooperation and thereby take collective action to provide collective benefits.

## Proactive Interference

Susana Carnero-Sierra and Paula Alfonso-Arias  
Universidad de Oviedo, Oviedo, Spain

### Synonyms

Competing cues; Interference; Memory; Paired-associated learning

### Definition

Proactive interference is the appearing of a problem in a new learning, induced by the recall of previous information. An example would be when two word lists are learned sequentially: first list A and list B after. Proactive interference occurs when it is required to recall list B, but words of the A list are recalled instead.

### Introduction

Proactive interference is a memory phenomenon present in daily life constantly (Baddeley et al. 2009). An example can be seen when the password of your e-mail account changes, but you keep typing the old one instead.

One of the first authors to mention proactive interference was Underwood (1957). In his studies, he asked participants to learn nonsense syllables, observing high levels of forgetting after 24 h. Underwood thought that it could be due to the hard demand of study tasks present in students that used to be the experimental subjects of his studies. The students used to participate in a lot of experiments in the university background, and so much memory stimuli could be interfering in the forgetting general rate.

To sort out this question, Underwood decided to replicate his study but using two different groups: an experimental group with subjects that have participated in several experiments before and a second control group that participated in

the experiment for the first time. Twenty-four hours after the learning of syllables, this author observed that the experimental group forgot a 75% of total stimuli presented, in contrast to control group, which forgot only 25%. Underwood concluded that previous information clearly interfered in new learnings.

At this respect, the concept of interference has been crucial in the mixed field between learning and memory. Interference paradigms in associative learning have been relevant in the way in which behavior scientists try to understand complex situations in the learning of stimuli association (Bouton 1993).

### Experimental Paradigm

In an associated-paired memory paradigm (Fig. 1), the proper design to study proactive interference consists in presenting word pairs in which the first element of the pair (called stimulus) and the second (response) are presented together (e.g., pencil-ring; being pencil the stimulus and ring the response). One group or experimental group is exposed to a set of paired words. After that, experimental subjects are exposed to a second list of word pairs, in which stimuli are the same of the first list, but the associated responses are different (e.g., pencil-window). Control group did not receive anything during the first phase but received the second list in order to compare the level of interference in experimental responses. In the test, the stimuli are presented in order to recover the associate response of the second list. The difference in recall between both groups will set the level of proactive interference (Fig. 2).

**Proactive Interference, Fig. 2** Example of stimuli for a pair-associated experiment to study proactive interference

**Variables that Modulate the Interference**

- ▶ [Paired-Associated Learning](#)
- ▶ [Retroactive Interference](#)

As it happens in other types of interference phenomena in memory, such as retrospective interference, a few variables are thought to be critical for the appearance of prospective interference. Similarity has been shown as a critical variable to modulate proactive errors. Specifically, the more similarity, the more interference will be observed. Another relevant factor to modify proactive interference is the delay between lists. Delays between stimuli, or between phases, in experimental sets in memory have been very useful to unravel memory processes.

### Definition

A broad set of mental processes aimed at overcoming an obstacle to achieve a goal in a context-specific situation.

### Introduction

Animals regularly encounter situations which require problem-solving skills, where trial-and-error learning and spontaneous “insightful” problem-solving lie at the opposite ends of the problem-solving spectrum. The trial-and-error is considered one of the least sophisticated forms of problem-solving and involves learning from the consequences of one’s behavior in a repeated process of trying various attempts until the desired goal is achieved. In contrast, the ability to solve problems from the first presentations is considered one of the most complex mental processes in animals. This so-called “insightful” problem-solving presumes considering possible outcomes before determining the correct solution involves the ability to mentally represent aspects of the environment and to manipulate these representations (Piaget 1954).

The distinction between the two forms has a long history of a comparative study of problem-solving. In his famous experiment, Thorndike (1898) placed a cat in a series of puzzle boxes which were enclosed but contained a release mechanism that, when operated by the cat, would allow the animal to escape and receive the

reward positioned just outside the puzzle box. He recorded how long each animal took to figure out how to escape from the box. Even though the first successful escape occurred simply by accident, the cats became likely to repeat the successful action because they had received an award immediately after performing this action. Thorndike noted that with each trial, the cats became much faster at opening the door suggesting that animals were solving the problem via trial-and-error learning rather than insight.

Since then, the interest in the roles of trial-and-error learning and insight in animal problem-solving have not decreased, and the question of what kind of information animals use when solving problems remains a controversial topic. A variety of tasks has been developed to assess specific types of problem-solving; most of them are based on a tool-use capacity.

### Tool-Use-Related Problem-Solving

Human and nonhuman animals often use tools to solve problems to obtain a visible but inaccessible reward (Köhler 1927). In fact, tool-use-related problem-solving has been found in all sorts of animals (Beck 1980), from a crab attaching anemones to their claws to protect themselves from predators and sea otters using stones as anvils to break mollusc shells to New Caledonian crows and chimpanzees using sticks to extract insects from tree holes or crevices. However, the underlying cognitive processes of tool-related problem-solving may differ.

Early experiments on tool-use-related problem-solving came from the primatologists. Visalberghi and Trinca (1989) designed a task consisting of a long horizontal transparent tube with a peanut in the middle and a stick that fits into the tube. When provided with the stick, the monkeys used them to obtain the food by inserting the stick into one end of the tube and pushing the peanut out. However, the monkeys solved the problem after initially trying to stick their fingers into the tube, detach the tube or break it open, and with increasing speed and efficiency, suggesting that poking

the stick into the tube was acquired through trial and error.

Thus, to test whether the animals understand the actual function of the tool, the task has been modified. In what became a benchmark paradigm to study tool-use-related problem-solving, a trap was introduced on one side of the peanut (Visalberghi and Limongelli 1994) such that if the stick were inserted into the wrong side of the tube, it would push the peanut into this trap making it inaccessible. Most monkeys failed to solve this task and lost the reward in more than 50% of their attempts, using a distance-based associative role and inserting the stick into the side of the tube farthest from the peanut. Since this pioneer work, a variety of species have been tested on the trap-tube task and variants of it, including great apes (Povinelli 2000), other primates (Santos et al. 2006), human children (Horner and Whiten 2007) and adults (Silva et al. 2005), as well as birds (Tebbich and Bshary 2004). Yet there was no conclusive evidence that nonhuman animals can use causal knowledge rather than associative learning to solve complex physical problems.

A more precise method identifying cognitive strategies animals use for problem-solving is presenting a subject with a transfer tasks after it successfully learnt an initial discrimination task. In the transfer tasks, arbitrary stimuli are changed, while the causal structure of the problem remains constant. Successful performance across transfer tasks eliminates the use of associative learning via trial and error and suggests the use of “insight.” In a study using novel trap-tube transfer tasks at least one rook, *Corvus frugilegus*, might have solved the trap-tube problem using causally relevant cues such as “surface continuity”, which means that objects can be moved on continuous surfaces and “object solidity”, which means that objects cannot be moved through each other (Seed et al. 2006).

## Proto-Tool Tasks

Although tool-related problems such as trap-tube task are widely used and accepted paradigms

used to investigate problem-solving strategies in animals, they are less suitable for large-scale comparative studies since the manipulative capacities of the most non-primate species are limited (Santos et al. 2006; Tebbich et al. 2007).

Thus, “proto-tool” tasks, in which the tool is connected to the reward from the beginning, are commonly used for a broader comparative approach (Krasheninnikova et al. 2013). In such tasks, a subject faces a choice between two or more options, one of which is physically connected to an out-of-reach object of desire. One of the most common tasks of this type is the “string-pulling task,” initially applied by Köhler (1927), and the “support problem,” initially introduced by (Piaget 1954). In the string-pulling task, a string is attached to a reward. The reward itself is out of reach of the animal, but the near end of the string is accessible. In the “support problem,” a reward is out of subject’s reach but is placed on a cloth which the subject can pull toward it. Both tasks – the string pulling and the support problem – are based on the assumption that if the animal understands the functional property of the string or the cloth, it will use it as a means to an end, i.e., spontaneously pulls the food into reach on its first exposure to the task. In contrary, subjects who do not understand that pulling the string is the “means” for achieving the desired “ends” of bringing the food within reach will only be able to succeed through repeated exposure and resulting associative learning (Range et al. 2012).

So far, a great variety of animals ranging from primates over dogs, cats, and elephants to birds and even insects have been tested with the string-pulling task and/or support problem. Spontaneous “insightful” solutions were found just in few species, for example, in a number of nonhuman primates (Hauser et al. 1999), large-brained birds such as corvids and psittacids (e.g., Auersperg et al. 2009; Heinrich and Bugnyar 2005; Krasheninnikova and Schneider 2014), and elephants (Irie-Sugimoto et al. 2008). Various cognitive processes have been proposed for different other animals, for example, associative learning (e.g., pigeons, *Columba livia* (Schmidt and Cook 2006) and bumblebee, *Bombus*

*terrestris* (Alem et al. 2016)), relying on perceptual feedback (New Caledonian crows, *Corvus moneduloides* (Taylor et al. 2009)), or attending to perceptual contact rather than connectivity (great apes, Povinelli 2000). Dogs and domestic cats (*Felis catus*), were able to learn to obtain food that was out of reach by means of a string, but failed to understand means-end relationships when tested in various patterned-string tasks (Osthaus et al. 2005; Whitt et al. 2009).

## Cooperative Problem-Solving

Social factors have been suggested to play an important role in problem-solving tasks (Melis et al. 2006). When other conspecifics are present, animals may solve problems through cooperative behavior.

Traditionally, cooperative problem-solving has been assessed in mammals, especially primates. The benchmark test of cooperative problem-solving, the loose-string paradigm (Hirata and Fuwa 2007), requires two subjects pulling the two ends of a string simultaneously to move a platform with reward toward them. A dyad's performance, thus, depends on the subjects' ability to coordinate their pulling action. So far, only chimpanzees, *Pan troglodytes* (e.g., Melis et al. 2006); bonobos, *Pan paniscus* (Hare et al. 2007); orangutans, *Pongo pygmaeus* (Chalmeau et al. 1997); capuchin monkeys, *Cebus apella* (Mendres and De Waal 2000); cotton-top tamarins, *Sanguines oedipus* (Cronin et al. 2005); Asian elephants, *Elephas maximus* (Plotnik et al. 2011); bottlenose dolphins, *Tursiops truncatus* (Kuczaj et al. 2014); wolves, *Canis lupus* (Marshall-Pescini et al. 2017); and spotted hyenas, *Crocuta crocuta* (Drea and Carter 2009) have been reported not only to cooperate to solve a problem but also at least some sensitivity to the need of a cooperative partner to do so. More recently, also several bird species have been tested in the loose-string paradigm with mixed results. While rooks and African gray parrots have so far shown no sensitivity to any task contingencies, ravens and keas were reported to fail additional tests in some studies

(Massen et al. 2015) and to succeed in others (Heaney et al. 2017).

## Future Questions

Many animal species are problem-solvers, but the underlying cognitive processes of the problem-solving may differ. Great apes, corvids, parrots, and some carnivore species appear to excel and show the spontaneous problem-solving in different contexts. Previous findings reveal striking similarities in underlying mechanisms of human and nonhuman problem-solving. Yet understanding taxonomic differences and similarities in cognitive aspects of problem-solving continues to be a significant research challenge. Proto-tool-based counterparts of the tool-use-related task allow us to test a broader range of species with different levels of brain development and manipulative capacities and help to expand our understanding of the problem-solving relevant cognitive abilities across various animal species. Nevertheless, most experimental paradigms described above present animals with specific problems and investigate how the animals solve them in order to examine specific cognitive processes (Auersperg et al. 2012). The majority of these typically started off from a single experiment designed for testing a particular species and some subsequently applied to other species. Consequently, only little attention has been paid to species-specific morphological and perceptual features, in addition to psychological variables such as motivational, emotional, or attentional states, inhibitory control, or neophobia (Auersperg et al. 2012).

A new approach to test animal problem-solving comparatively is the multi-access box (Auersperg et al. 2011). It presents a subject with a novel problem that can be solved in different ways, i.e., it consists of a battery of different tasks that all lead to the same goal. This approach offers a unique possibility to examine how novel problems are perceived, explored, and approached across different species. The multi-access box approach is a helpful tool in establishing behavioral and psychological profiles

of the species to be compared. Future comparative research using this approach may help to identify problem-solving tasks that are equivalently applicable across a broader range of different species and allow a high degree of “comparability” of the data obtained from different taxa (Auersperg et al. 2012).

Along with other cognitive abilities, the problem-solving abilities are most likely determined by the level of taxa-specific brain development rather than the presence of species-specific adaptations in some species. Thus future studies on problem-solving should consider species’ brain anatomy to disentangle the physiological correlates of problem-solving behavior in various taxa. Finally, social influences in problem-solving should be studied more intensively to determine how and when individuals may cooperate to solve problems.

## Proboscidea

### ► Elephant Life History

## Proboscidea Cognition

Preston Foerder  
Chattanooga, TN, USA

## Introduction

Proboscidea refers to the order that includes elephant species. The term proboscidea comes from

proboscis, the elephant's trunk or nose being their most distinct feature. The order includes 161 extinct species of proboscideans and the three extant species in the family Elephantidae. The three living elephant species are Asian elephants (*Elephas maximus*) African savanna or bush elephants (*Loxodonta africana*), and African forest elephants (*Loxodonta cyclotis*). Until the beginning of the twenty-first century, the African elephants were considered a single species but have since been determined to be two separate species based on behavior, morphology, and genetics (Shoshani and Tassy 2005). In 2021, the International Union for Conservation of Nature (IUCN) recognized the differences in the two African species, changing their conservation status from "vulnerable" as a combined species to "endangered" for African savanna elephants and "critically endangered" for African forest elephants (IUCN 2021). The IUCN also lists Asian elephants as "endangered."

Animal cognition involves "the mechanisms by which animals acquire, process, store, and act on information from the environment" (Shettleworth 2010, p. 4). Anecdotal tales of elephant cognitive abilities go back centuries. Romanes (1882) tells of an elephant that chased people up a tree and then stacked logs under the tree until it could climb the stack to almost reach them. (Fortunately for the people, there were not enough logs.) However, a 2009 review of peer-reviewed journal articles on elephant cognition going back to 1956 found only 21 papers (Byrne et al.). Since that time, research on elephant cognition has advanced more rapidly.

## The Elephant Brain

As the largest terrestrial mammal, the elephant unsurprisingly has the largest brain of any terrestrial mammal (Shoshani et al. 2006). The elephant brain is roughly three times heavier than the human brain and contains about three times the number of neurons. The elephant brain also shows a more complex gyral structure (more folds in the brain) than the primate brain; however, the cerebral cortex is thinner than a human's. The

elephant's hippocampus (the brain structure associated with learning and memory) is proportionately larger, and the elephant has an extremely large cerebellum, the smaller "brain" behind the cortex. Although the elephant has a greater total number of neurons, the majority of these (97.5%) are in the cerebellum rather than the cerebral cortex. The cerebellum is generally associated with fine motor movement, and its size in the elephant may be due to the complexities of controlling the trunk (Herculano-Houzel et al. 2014).

## Sensation and Perception

The elephant's primary senses are hearing (audition) and smelling (olfaction). Their upper range reaches 10 kHz, compared to 19 kHz in humans. On the lower end, they can hear infrasound as low as 17 Hz (perhaps lower) compared to 29 Hz in humans (Suedemeyer 2006). Elephants are the first terrestrial mammals found to use infrasonic communication (Payne 1998). They also can sense seismic communication from the earth. Massive ossicles (bones in the inner ear) may allow them to hear sound using bone conduction from their feet (O'Connell-Rodwell 2007).

Along with hearing, elephants rely on olfaction. The Asian elephant has seven turbinates, the chemosensory-lined bony plates in the skull. Comparatively, dogs have five turbinates, and humans have three (Shoshani 1997). Rasmussen described the sensitivity of the elephant olfactory system as "awesome" (2006). Elephants have approximately 2000 genes for olfactory receptors, twice as many as any other animal tested (Niimura et al. 2014). Elephants use pheromones to discriminate individuals, relationships, sexual states, and group status (Rasmussen 2006).

The elephant's primary appendage for touch is the tip of the trunk. The concentration of touch receptors in the trunk has been compared to the lip skin of monkeys. There are two types of vibrissae attached to hundreds of sensory neurons. This sensitivity may enable the trunk tip to pick up small objects (Rasmussen 2006; Rasmussen and Munger 1996). The tip is sensitive enough to

grasp items the width of a needle (Shoshani 1997). Rasmussen (2006) called the trunk tip a “refined eating tool.”

Although vision is not the elephant’s primary sense, Pettigrew et al. (2010), estimated that the elephant’s vision is better than previously supposed. Elephants are dichromatic, comparable to human deuteranopes (red-green colorblind). Their vision is thought to be more sensitive in dim rather than bright light (Yokoyama et al. 2005) and good enough to see the many postural gestures of elephant communication (Byrne et al. 2009). Elephants’ visual sensitivity is less than a human being’s but better than a cat’s. Asian elephants may have higher visual acuity than African elephants (Shyan-Norwalt et al. 2010). Taking into consideration the differences between elephant and human sensation and perception is one of the great challenges of research on proboscidea cognition.

## Discrimination

In discrimination tests, animals show that they can tell the difference between different stimuli (symbols, objects, sounds, colors, and odors). They discriminate by classifying and categorizing the stimuli (Shettleworth 2010). In some of the first scientific research on elephant cognition, an Asian elephant learned to discriminate between two visual symbols, a circle and a cross, over 330 trials. The elephant was reinforced with food for touching the cross. Eventually, the elephant could learn this discrimination in 10 trials and also learned to discriminate between 20 different pairs of symbols, different sound frequencies, and orders of notes (Rensch 1957). It was later found that elephants could retain a learned discrimination between light and dark circles for 8 years (Markowitz et al. 1975).

In a series of experiments on wild African savanna elephants, researchers showed that elephants can discriminate between two different tribes, one that threatens elephants (the Maasai) and one that does not (the Kamba). The elephants displayed behavioral fear reactions to visible, olfactory, and auditory stimuli, discriminating

individuals from the two tribes, from the look of their clothing, their odor, and the sound of their languages. The elephants could also distinguish men (a greater threat) from women based on the sound of their voices (McComb et al. 2014).

## Numerosity

An animal can also discriminate between different quantities (usually food in the research studies). This ability is also known as relative quantity judgment. Initial research on Asian elephants was conducted through two experiments on relative quantity judgment. In the first experiment, the elephants were shown different amounts of food in two different buckets and could choose between them. The elephants chose the larger amount at greater than chance levels. In the second experiment, the elephants heard the food dropped into the buckets one piece at a time. In this experiment, the elephants also chose the greater amount. In both experiments, the elephants could also smell the food. The researchers did not see magnitude nor ratio effects, which is typical in relative quantity judgment tasks in animals. In the magnitude effect, success in the task diminishes when using larger numbers of items. In the ratio effect, the success decreases when the difference between the numbers is closer (i.e., 2 to 4 vs. 3 to 4). The study may have found that elephants were the first animals tested that did not show the ratio effect (Irie-Sugimoto et al. 2009).

This research was later replicated by others on African savanna elephants. They had similar results; however, the African elephants showed a ratio effect. They also later tested other Asian elephants on a similar study and, once again, found a ratio effect and no difference in results between the species. Another researcher conducted the experiment using only olfactory cues, and found that elephants chose the larger amount but also showed a ratio effect (Snyder et al. 2021). Finally, the original researchers tested an Asian elephant on purely visual stimuli on a touch screen. Once again, they found that the elephant chose the larger quantity and did not

show a ratio effect. The researchers posited that Asian elephants are better at quantity judgment than African elephants, a result later contradicted by the study that compared the two species (Irie et al. 2019). Further research will be needed to ascertain the elephants' quantity judgment abilities.

## Problem-Solving and Tool-Use

One aspect of intelligence is the ability to solve problems. In animals, the goal is to establish evidence that the animal has a sense of causality, that it understands what it is doing and is not merely repeating previously learned behaviors. One way this has been tested in elephants is through the means-end problem, knowing that when you pull one end of an object that something placed on the opposite end will come with it. The elephant is given a choice of two trays with food. In one condition, the food is on the tray. In another condition the food is next to the tray, or there is a split in the tray. African and Asian elephants have shown an understanding of this relationship in many experiments by primarily pulling the intact tray with the food on it, although not all elephants succeeded at all conditions (Highfill et al. 2018; Irie-Sugimoto et al. 2008).

Tool-use was first thought to be an exclusively human trait until Jane Goodall saw chimpanzees using sticks to "fish" for termites (van Lawick-Goodall 1970). Since then, tool-use has been found in many species. Elephants have shown the broadest use of tools of any animal outside of primates. In a review of elephant tool use in elephants, Chevalier found 21 examples in captive elephants and 9 in wild elephants, including fly swatting, scratching with objects, and throwing water or dirt on the body (Chevalier-Skolnikoff and Liska 1993). Elephants can disable electric fences by dropping logs on them (Poole and Moss 2008) and alter branches to use as fly swatters (Hart et al. 2001). Elephants' primary asset for tool-use is their extraordinarily manipulable trunk.

Problem-solving through tool-use was first studied through a series of experiments on

chimpanzees in the early twentieth century (Köhler 1925). Köhler termed this type of problem-solving as insight because he could see no evidence of trial-and-error learning in the solution. In a series of experiments, three Asian elephants were tested for their ability to solve insight problems with tools. In two different experiments, the elephants were given sticks to obtain food that had been placed out-of-reach. The elephants pulled the sticks into their stalls and manipulated them in many ways but never used them to acquire the food. The researchers decided that the elephants were unlikely to use the sticks because holding the sticks in their trunks blocked the elephants' two primary senses for foraging: touch and smell. The elephants were then given another tool that they did not have to hold with their trunks: a platform that they could move and stand on to reach food that was placed overhead. One elephant, a 7-year-old male, moved a large plastic cube under the food so that he could stand on it and obtain the food. Through a series of experiments, he found the tool in a wide range of places and moved it under the food. He generalized his tool-use to another item, a large truck tire, which he moved and stood on to acquire the food (Foerder et al. 2011).

## Social Cognition

Elephant intelligence may have evolved to deal with the complexities of their fission-fusion social systems. This type of intelligence has become known as social intelligence. Byrne and Whiten (1997) coined the term "Machiavellian intelligence," the theory that intelligence is "linked with social living and the problems of complexity it can pose" (p. 1). African elephants can follow the locations of up to 30 family members, which demonstrates their memory and ability to categorize (Bates et al. 2008).

*Social Learning.* Although there is observational evidence of elephants that appear to be learning from each other in the wild, there has been little experimental evidence of social learning in elephants. In one experiment on six captive African savanna elephants, an elephant was given

a box containing food with two different ways to access the food. Another elephant watched the first elephant use one of the methods to open the box. The researchers wanted to see if the second elephant used the same method. The second elephant did not show mimicry, copying exactly the demonstrator elephant. However, the observer elephant was more likely to investigate the box and acquire the food. This type of social learning is known as stimulus enhancement. The observer's attention was brought to the box by the demonstrator increasing the observer's likelihood of obtaining the food (Greco et al. 2013).

**Cooperative Problem-Solving.** In cooperative problem-solving, two animals are given a food acquisition problem which can only be solved by them working together. The animals are given a sliding tray with food that can only be obtained by the two animals pulling on the rope at the same time. If one pulls on the rope, the rope will come loose and the food will remain out of reach. This problem was given to Asian elephants. The elephants were capable of pulling together to acquire the food. If one elephant approached the apparatus before the second one, the first would wait for the second's arrival before pulling. There was even one elephant who learned how to cheat. She found that if she stood on the rope while the other elephant was pulling she could obtain the food without much effort (Plotnik et al. 2011).

**Mirror Self-Recognition.** The ability to recognize oneself in a mirror is known as mirror self-recognition (MSR). It is thought that MSR may be an indication of consciousness in nonhuman animals. MSR has been shown not only in humans but also great apes, dolphins, and magpies. While some researchers have reported negative results for MSR in elephants, methodological problems may have hampered the elephants showing the ability. The standard test for MSR is the mark test in which a mark is placed on one side of the animal's face. The animal is then observed to determine if it touches the mark upon seeing itself in the mirror indicating that it recognizes itself. Three Asian elephants at the Bronx Zoo were tested and all three showed self-directed behavior in the mirror and one passed the mark test, providing evidence for MSR (Plotnik et al. 2006).

## Conclusion

Elephants have shown a wide range of cognitive abilities. Comparison of cognition between humans and other primates involves divergent evolution. How did human cognitive abilities diverge from other animals? Studying elephant cognition involves convergent evolution. How did an animal so different from humans, and so far from them on the evolutionary scale, evolve similar cognition? Considering that both species have complex societies, and large brains to deal with them, may have led to the cognitive similarities. However, there is still much to learn about proboscidea cognition and many avenues for future research.

## Proboscidea Communication

Joy Vincent  
Oakland University, Rochester, MI, USA

### Synonyms

[Elephant communication](#)

### Definition

The order Proboscidea consists of three extant species, the Asian elephant and two subspecies of African elephants. Communication is the exchange of information, accomplished through a variety of modalities, including vocalizations, chemical signals, and behavioral cues.

### Introduction

The order of Proboscidea was historically widespread, consisting of many different species. However, the order has diminished, now comprising only three extant species: the Asian elephant (*Elephas maximus*) and two subspecies of African elephants (*Africana loxodonta*) (Soltis 2010). These two genera are believed to have diverged from one another nearly six million years ago, resulting in slight differences in their ecological niches and social structures (de Silva 2010).

Both African and Asian elephants exhibit complex societies, characterized by matriarchal family groups that periodically overlap with one another within their home ranges (de Silva 2010). This

gives rise to what is known as a fission-fusion society, wherein closely bonded family groups will join together when resources allow and diverge from each other when resources are scarce (Soltis 2010). Such social structures necessitate a well-developed system of communication. It has been suggested that increased social complexity correlates with increased communicative complexity (Meyer et al. 2008). This pattern seems to hold when considering the complexity of the extant Proboscideans.

Elephants have highly developed senses, which are all put to use in intraspecific communication, including their senses of sight, hearing, smell, and touch. Research suggests that many of these senses are often used in concert, lending to the increased complexity of their communicative abilities (Langbauer 2000). Anatomical adaptations have increased their sensitivities to a variety of sensory inputs (O'Connell-Rodwell 2007), enabling elephants to communicate through a multitude of mechanisms including vocal, chemical, and visual. While there is evidence of communication through various modalities, vocal communication is the most widely studied and understood mechanism.

### Vocal Communication

The vocal repertoire of elephants is marked by low frequencies and high pressures (Poole et al. 1988). These characteristics are believed to be adaptive for longer distance communication and coordination, whether it be within a family group or broadcast over a great distance to other groups and individuals (Poole et al. 1988). The production of these distinct calls may be possible due to enlarged anatomical structures, such as their diaphragms and nasal cavities, which are central to noise formation (O'Connell-Rodwell 2007).

A majority of vocalizations made by elephants are inaudible to the human ear (Langbauer 2000), because their fundamental frequencies fall within the infrasonic range of 15–35 Hz (Poole et al. 1988; Langbauer 2000; McComb et al. 2000). Their calls can also reach pressure levels as high as 103 dB at 5 m from the source in one study

(Poole et al. 1988), and 118 dB at 1 m in another (Langbauer et al. 1991). There is much variety in the fundamental frequencies, harmonics, and durations of different types of calls in their repertoire (Stoeger and Baotic 2016). A majority of calls, however, persist for approximately 10–15 s, with frequencies in the range of 14–24 Hz and sound pressures of 85–90 dB (Payne et al. 1986).

Variations in elephants' vocalizations can reflect a variety of features, including individual identity, affect, and reproductive status (Soltis et al. 2005b; Soltis 2010). Increased fundamental frequencies have been linked to increased levels of arousal in numerous species (Stoeger et al. 2012). Calls with higher pitch appear to be correlated with increased levels of arousal; elephants generate more high-frequency calls during periods of high excitement, such as aggression and mating, as compared to calmer contexts (Soltis et al. 2005b).

In addition to increased fundamental frequencies during periods of high arousal, structural features of calls are linked to more adverse contexts, such as dominance interactions (Stoeger et al. 2012). During dominance interactions, the rumbles tend to have lower tonality, less pitch stability, and formants that are closer together than rumbles in calmer circumstances (Soltis et al. 2005b; Stoeger et al. 2012). Moreover, there is a characteristic upward modulation of the second formant in calls that alert others to potential danger (Stoeger et al. 2012).

Although numerous specific calls have been described in the literature, there is a level of disconnect because of incongruity in the naming and descriptions of different vocalizations. This has led to a lack of consensus in the number of vocalizations that have been documented and can be reasonably discerned from other calls. Out of 209 vocalizations, Berg (1983) identified ten unique types of calls. In 1988, Poole outlined seven distinctive types of rumbles that differed in both their acoustic characteristics and their overt social function. More recently, Leong et al. (2003) determined that there were eight types of vocalizations, three of which were distinct rumbles. Other data suggest that there are actually nine types of calls (Soltis 2010). Despite the

inconsistencies in the total number of distinguishable call types, there seems to be greater agreement on the calls in a broader scope; there are six types of calls that can be differentiated from each other. These calls are the rumble, the bark, the grunt, the roar, the snort, and the trumpet (Stoeger et al. 2007).

### Rumble

The most common and varied type of vocalization is the rumble. This laryngeal call is common in both adults and juveniles of both sexes. There are many types of rumbles, classified based on their context in addition to their vocal attributes (de Silva 2010). One such call known as the “let's go” rumble has a fundamental frequency of 15 Hz and sound pressure of up to 63 dB at 25 m (Poole et al. 1988). This call accompanies a series of behaviors used to indicate the intention for the group of individuals to move on from a given location. The call is made by an individual standing toward the edge of the group, with one foot raised and ear flapping. This call signals the other members of the group that they are leaving, and they depart together.

Another common type of rumble is the “greeting” rumble. This call has a fundamental frequency of 18 Hz, which modulates up to 25 Hz and back down to 18 Hz, with a sound pressure of 61 dB at 20 m (Poole et al. 1988). Greeting rumbles, particularly when made after a longer period of separation, spark an impassioned response, including overlapping rumbling and trumpeting from members of the group, physical contact, and defecating and urinating (Poole et al. 1988). This series of behaviors associated with “greeting” rumbles may play an important role in maintaining relationships within and between family groups.

Rumbles accounted for 53% of juvenile calls in one study (Stoeger et al. 2007). Juvenile rumbles have incredible variability in their bandwidths ranging from 70 Hz up to 2000 Hz. Those on the lower end of the spectrum are often produced with their mouths closed and commonly result in a vocal response from their mother, whereas louder calls, commonly produced with the mouth open, often necessitates a more immediate response, as they signal distress or protest (Stoeger et al. 2007).

**Bark**

Barks are specific to juveniles and are non-repetitive, abnormal vocalizations that seem to occur in concert with aggressive behaviors, such as pushing or biting (de Silva 2010). It is often produced when the juvenile is surprised, such as when they are kicked or pushed. It is a rapid, noisy call that results from the expulsion of air from their oral cavity and is produced with the mouth wide open (Stoeger et al. 2007).

**Grunt**

The grunt is a laryngeal call that is specific to juveniles. They are soft calls, often produced with their mouths closed. Their structure is stereotyped with only the first inklings of harmonics (Stoeger et al. 2007).

**Roar**

Roars are used in a variety of settings; commonly, they are heard during group movement, but also during instances of high distress. They are the most common distress call used by all ages, but particularly juveniles (Stoeger et al. 2011). Roars are formulated with the larynx and are uttered with their mouths wide open (Stoeger et al. 2007). In adult elephants, a subtype of roar with an increased duration is known as a longroar. This call is commonly associated with higher levels of distress, particularly when an individual is separated from the group. Longroars often accompany behaviors associated with increased levels of arousal: increased speed, head lifted, and tail erect (de Silva 2010).

Roars produced by juveniles account for the highest pitch of any vocalization in African elephants, reaching fundamental frequencies higher than 390 Hz (Stoeger et al. 2007). In juveniles, there are three subtypes of roars. The most stereotyped roar is the noisy roar, which is a subtype characterized by being noisy and lacking tonality. Noisy roars often coincide with some sort of distress requiring immediate attention. Tonal roars, in contrast, are tonal for the majority of the call and less stereotyped than noisy roars. Mixed roars incorporate elements of both noisy and tonal roars and lack any stereotyped structure. Tonal and mixed roars were often produced in response to

suckle terminations, rather than immediately distressing events (Stoeger et al. 2007).

Chaos is a type of nonlinear phenomena (NLP) in vocalizations that affect the call in such a way as to deviate from the normal vocal pattern. It occurs when both the vocal tract fold tension and air pressure increase, causing abnormalities in the vibrations and subsequent vocalization (Stoeger et al. 2011), when an individual is pushing their vocal capacities past their limits. NLP was observed in 92% of juveniles' roars, suggesting a link between NLP and increased levels of distress (Stoeger et al. 2011). It has been hypothesized that chaos makes juveniles' calls less predictable and harder to become accustomed to, increasing the likelihood that their mother will be able to respond quickly to the distressing situation. The tonality of roars decreases as the severity of the distress increases, meaning that there is more noise and less harmonics during these periods (Stoeger et al. 2011).

**Snort**

Snorts result from a strong blast of air through the trunk and occur in all ages and sexes. Snorts lack any tonality and do not seem to have a specific function in communication. Researchers argue that they serve a cleaning function, rather than a communicative function (Stoeger et al. 2007).

**Trumpet**

Trumpets are quintessentially Proboscidean, described by researchers as having long durations and high sound pressures. Whereas trumpets make up only a small percentage of elephants' vocalizations, they are the call type most readily associated with elephants because they are audible to humans (de Silva 2010). They do not develop until 3 months and are often produced in concert with aggressive interactions. Produced nasally, trumpets are tonal with slight harmonics (Stoeger et al. 2007).

**Growls**

Growls are associated mainly with family groups, as males do not seem to exhibit this type of call. Growls are distinct to the individual caller; thus they are believed to be central in locating

individuals and maintaining group cohesion over distances (de Silva 2010).

### Contact Calls and Answers

Contact calls are important in maintaining cohesion and coordination within family groups. While they are audible to the human ear, they sound relatively soft (Poole et al. 1988); contact calls have an unmodulated frequency of approximately 21 Hz and last 4–5 s (McComb et al. 2000). Contact answers are responses to contact calls, often starting loud and tapering off to a softer sound at the end of the call (Poole et al. 1988). In a playback experiment, contact calls from members of a family group resulted in both contact answers and an inclination to move toward the speaker (Langbauer 2000). Contact calls and answers are crucial in the coordination of group movement as well as the reunion of individuals. When separated from their group, an elephant may engage in contact calling for many hours in an effort to be reunited (Poole et al. 1988).

### Group Coordination

Vocal communication is central to the coordination of elephant herds over great distances. Vocalizations are omnidirectional, spreading in all directions and over great distances (Langbauer 2000). Family groups of African elephants will often vocalize in unison, creating a signal that can propagate nearly three times farther than that of a single elephant (O'Connell-Rodwell 2007). Analysis of the movement of various radio-collared elephants in different family groups revealed that they are able to coordinate their movement within and between family groups over a distance of up to 5 km (Langbauer et al. 1991; Poole et al. 1988).

This coordinative ability is of particular importance to African forest elephants. Their habitat, consisting of thick vegetation, makes it nearly impossible to rely on visual contact in maintaining group cohesion. These groups can grow to be over 100 m in diameter, necessitating a nonvisual mechanism for coordination (Payne et al. 1986).

Vocalizations among conspecifics are not relegated solely to in-group members but are also used in coordinating with other family groups. Separate family groups have been observed assembling prior to their arrival at waterholes (Garstang et al. 1995). While the specific function of this synchrony is unknown, it is hypothesized that it may serve as an antipredatory function.

Such coordination between groups may also serve to alleviate competition over resources (Garstang et al. 1995). Family groups have been observed coordinating their movements over distances of several kilometers without ever converging. This pattern may serve to ensure the groups are sufficiently separated to minimize competition, while maintaining a distance at which they can mutually benefit from predator monitoring (Langbauer 2000). The ability for their low frequency vocalizations to propagate over long distances in every direction allows families to maintain sufficient separation from one another while reaping the benefits of increased numbers (Garstang et al. 1995).

### Vocal Discriminations

#### Familiarity

There are many characteristics that can be discerned from an individual's vocalizations. Formant frequencies are directly related to body size and, more specifically, vocal tract length (Stoeger et al. 2012). Sex, status, and even individual identity can also be garnered from information encoded in elephants' calls. McComb et al. (2000) demonstrated the ability of elephants to discriminate between familiar and unfamiliar elephants. In 2003, McComb outlined the first evidence that certain features of rumbles held the key to discerning individuals' identities.

#### Individual Recognition

Elephants appear to have an extensive vocal recognition network, demonstrating the ability to discriminate between individuals in their family group, bonded group members (individuals in another closely associated family group), less associated group members, and unfamiliar

individuals (McComb et al. 2000). It is likely that this extensive network of vocal recognition is a vestige of their fission-fusion society. It is necessary for individuals to have a working memory of numerous individuals with whom they may associate. In Amboseli National Park, adult females may have familiarity with 14 different families with whom they may come into contact (McComb et al. 2000).

### **Dominance**

Vocal communication is not only important in coordinating behaviors within and between groups, but also maintaining group cohesion and social order. In this vein, it is important for individuals to be able to communicate information about status within their group's hierarchy. A number of vocal tendencies have been observed in the context of dominance interactions. Individuals that are more dominant tended to vocalize when being aggressed upon, whereas those of lowing social standing remain silent. Researchers postulated that higher ranking individuals are more likely to vocalize as a way to assert status, whereas the goal of more subordinate individuals is to deescalate the situation (Leong et al. 2005). Another tendency is for the rumbles of subordinate individuals to have lower tonality and less pitch stability when dominant individuals are present as compared to when they are alone or in the presence of comparable or more subordinate individuals (Soltis et al. 2005b).

### **Antiphonal Calling**

Antiphonal calls are a series of back-and-forth calls between two or more individuals either in response to an initial call or some external stimulus (Soltis et al. 2005a). In a herd of captive elephants at Disney's Animal Kingdom, researchers found that the most common cause of antiphonal calling, at 31.7% of the cases, was the approach of a third-party individual who, most of the time, was dominant to at least one of the participating vocalists. While the response to an approaching dominant conspecific elicited a series of calls, the probability of an individual responding to a call was unrelated to their

dominance ranking; instead it was an individual's affiliation with the caller that predicted their response (Soltis et al. 2005a). Of the calls that were answered, 37.7% were by the individual most closely affiliated with the caller, followed by 31.9% being answered by the second most affiliated individual and 20.5% by the third most affiliated individual (Soltis et al. 2005a). Researchers also examined the conditions under which rumbles were produced. They found that individuals were 1.88 times more likely to vocalize following a rumble from a conspecific than when there were no recent calls (Soltis et al. 2005a). In the wild, it is uncommon for a female's call to go unanswered, as the majority of vocalizations occur in chorus with other group members (Langbauer 2000).

### **Male Communication**

Female elephants are highly social, living in complex matriarchal family groups. Males, on the other hand, exhibit far less social complexity, and their communication seems to reflect this difference. Males produce less varied vocalizations than females (Langbauer 2000). Once males reach sexual maturity, they leave their families and live on their own or in small bachelor herds of similarly aged individuals (Langbauer 2000). When they are not in musth – a period of increased androgen levels and aggression – males form a social structure of closely affiliated companions with a simple dominance hierarchy (Stoeger and Baotic 2016). These groups are relatively fluid, as they disband and reform as they cycle through their periods of musth each year (Meyer et al. 2008).

Although males leave their native family herds when they come of age, they will take up residence in ranges that overlap with a number of family groups (Langbauer 2000). This makes it important for males to be able to discriminate between individuals' vocalizations. As with females, males are able to extract information from conspecific vocalizations (Stoeger and Baotic 2017). This information, however, serves different functions for males (Stoeger and Baotic

2016). One of the most important functions of individual recognition on the part of males is differentiating between related and nonrelated individuals, so as to avoid inbreeding (Stoeger and Baotic 2017).

In a playback experiment, males preferred the rumbles of unfamiliar elephants rather than those from their native herd. This preference was marked by increased attention and orienting responses. In some instances, when presented with a call from an unfamiliar female, the males would entirely cease what they were doing, lift their head and move in the direction of the speaker (Stoeger and Baotic 2017). Males have an incredible ability to pinpoint the location from which a vocalization sourced. In another playback experiment, males passed within 100 m of the speaker following a trek of over 1 km from where they first heard the call (Langbauer et al. 1991).

Musth begins around the age of 25–30 years and recurs annually with increasing duration each year until they reach their peak (Meyer et al. 2008). Musth not only has an effect on males' reproductive success – with 75–80% of all offspring resulting from a musth male – but it also impacts the interactions between males (Stoeger and Baotic 2016). Although bachelor herds have a level of hierarchy, individuals in musth supersede this hierarchy, with musth males having increased access to mates compared to non-musth males (Slade et al. 2003). This ability to jump the hierarchy is rendered moot when they are not the only male in musth. In this situation, musth males have an uncanny ability to avoid one another while in search of a receptive mate, coming into contact only when necessary, often resulting in a fight for dominance in a mating context (Poole et al. 1988).

## Reproduction

Vocalizations specific to the context of courtship and mating impart information about the caller's physiological state and receptiveness, coinciding with musth in males and estrus in females (Langbauer 2000). Musth rumbles are produced by males during their period of musth that can last up to 4 months. They are a pulsated call with a low

frequency of 11–17 Hz and pressures of 78 dB at 5 m up to 108 dB (Meyer et al. 2008; Stoeger and Baotic 2016). They last for an average of 4.4 s and are often accompanied by a loud ear flap (Poole et al. 1988). When in range of a group of females, musth rumbles are often answered by a female chorus (Poole et al. 1988).

The female chorus is characterized by several females vocalizing in unison in response to a male's musth rumbles. They have a fundamental frequency of 15 Hz, which increases to 24 Hz before returning to 15 Hz, and a pressure of 88 dB at 16 m (Poole et al. 1988). Estrus rumbles are produced by females during her short period of estrus, which lasts approximately 5 days. Estrus rumbles have a relatively high-pressure level of 117 dB at 1 m and a fundamental frequency of 15 Hz, modulating up to 35 Hz and then back down to 15 Hz (Langbauer 2000). This call lasts for about 5 s and then repeats. Elephants may repeat this pattern for up to 30 min with progressively decreasing pressure levels. The unique frequency modulation of the estrus rumbles helps it to be differentiated from background noises (Langbauer 2000). Not only do they increase the duration of their calls during estrus, they also increase the frequency with which they make estrus calls, in an effort to increase their chances of attracting a mate (O'Connell-Rodwell 2007). It is crucial for females to find a mate during the incredibly short period of estrus. The uniqueness of the call, coupled with the high-pressure levels, help accomplish this goal. Estrus rumbles can be heard for at least 4 km (Langbauer 2000). While being guarded by a male, estrus females will often produce additional rumbles in an attempt to attract other males. The rationale behind this behavior is that it could induce a competition among the males, ensuring that she is mating with the highest quality mate (Soltis 2010).

In addition to musth and estrus rumbles, there are two additional vocalizations associated with the specific act of mating. Once a female has been mounted, she will produce what is known as a post-copulatory or estrus sequence. This is a series of two or more low-frequency calls that modulate from 18 Hz up to 35 Hz and back down to 18 Hz, with pressure levels of 96 dB at 10 m (Poole et al.

1988). Following this series of vocalizations, a sequence of behaviors known as mating pandemonium occurs. In this, the other females in the herd run to the female who was mounted while trumpeting, rumbling, and screaming, along with urinating, defecating, and secreting temporin from their temporal glands. This pandemonium can reach prolonged pressure levels of 78 dB at 67 m (Poole et al. 1988).

Some research has suggested that female vocalizations may differ based on where they are in their estrus cycle. Clemins and Johnson (2003) found that there were acoustic differences in the calls made by females in their follicular and luteal phases (cited in Leong et al. 2005). Not only is there an increase in the frequency of calls in the weeks leading up to ovulation, but there are specific patterns in their vocalizations in the preovulatory phase that are distinct from other parts of their cycle. In particular, these calls have, overall, lower fundamental frequencies in addition to both lower frequencies and higher amplitudes on their first formants than normal calls (Soltis 2010). These features may play a central role in propagating their calls longer distances during this pivotal time in a female elephant's reproductive cycle.

## Chemical Signaling

Vocal communication in elephants has adapted to suit their environment and carry over long distances; however, there are other mechanisms of communication that are able to serve similar purposes. Chemical communication can be used in both long- and short-distance communication, particularly with respect to signaling different physiological states. Urine and feces are energy-efficient and passive routes of chemical communication (Langbauer 2000; Slade et al. 2003). One of the most common iterations of this method is a hallmark of musth. The urine dribble is characterized by urine continuously flowing from the male's sheathed penis, leaving a trail of strongly scented urine wherever they go (Langbauer 2000). Another characteristically male chemical signal that functions over a much shorter distance

is the ear wave. Simplistically, the male extends their ears to the sides and rapidly brings them forward. This behavior concentrates the chemical signals sourcing from their temporal gland and focuses in a certain direction. This can be agonistic toward other males or an advertisement toward potential mates (Langbauer 2000).

Flehmen is a behavior wherein an elephant touches the tip of their trunk either to another elephant's mouth or urogenital region, or a substance in their environment. Then they deposit some of the sample from the tip of their trunk to the opening of the vomeronasal organ on the roof of their mouth. This organ is able to differentiate between different compounds in the sample, providing the individual with information about the source (Langbauer 2000). Females tend to exhibit this behavior toward urine from males in musth more than those not in musth, with females in estrus performing the most flehmens of musth urine (Langbauer 2000). Urogenital region checks are the most frequency of the many trunk tip behaviors common in elephants (Slade et al. 2003).

## Environmental Factors

A major fault with acoustic communication is its rapid degradation through an environment, experiencing interference from a variety of environmental features (Langbauer 2000). This is a far more pressing issue with higher frequency sounds than low-frequency sounds. Lower frequency sounds, such as those produced by elephants are far less subject to this environmental attenuation and are able to travel greater distances than higher frequency vocalizations at similar pressure levels (Poole et al. 1988). Substrate-borne transmission is also more resilient to air-borne attenuation; the low-frequency, high pressure vocalizations of elephants allow their vibrations to travel seismically over the ground (O'Connell-Rodwell 2007). Additionally, this method of transmission is able to provide information on how far the source is from the recipient, as the level of harmonics in the vibrations decreases over distance at a reliable rate (Langbauer 2000; O'Connell-Rodwell 2007).

There are a number of optimal conditions under which elephants can communicate. These conditions lend evidence to the manifestation of different behavioral patterns. Elephants are able to communicate at night more than twice the distance that they can during the daytime, with the optimal times being 1–2 h after sunset (Garstang et al. 1995). There are temperature inversions during the nighttime that force low-frequency sounds back to the ground, enhancing their communicative abilities (Garstang et al. 1995; Langbauer 2000). Bonded groups converge and travel to waterholes together commonly just before sunrise or just after sunset, suggesting that there is some communicative benefit to these periods of the day (Garstang et al. 1995). There have also been observed increases in elephant vocalizations near and after dusk (Langbauer 2000).

Some climactic conditions actually aid in communication. Clear, dry conditions, typical of dry seasons and droughts, are ideal for producing the temperature inversions during the night that enhance vocal communication. During such periods, enhanced vocal capabilities are crucial in ensuring that elephant herds maintain greater distances between themselves so as to limit resource competition when food and water is scarce (Garstang et al. 1995). The habitat of the African savannah elephant provides ideal conditions for enhanced sound conduction (Garstang et al. 1995). Under optimal conditions – dry, clear, and shortly after dusk – it is believed that vocalizations could travel up to 10 km in any direction (Garstang et al. 1995; Soltis 2010).

## Physiology

Elephants have unique anatomical features that allow them to effectively communicate over great distances (O'Connell-Rodwell 2007). One such feature is associated with their ability to detect seismic signals, either via mechanoreceptors in their skull or through bone conduction leading up from their feet. A series of fatty deposits couples with open sinuses in their skull that are believed to be central in detecting and

interpreting seismic signals. These fatty deposits may function as a way to clarify the signals they are receiving (O'Connell-Rodwell 2007).

Bone conduction is made possible through specific freezing behaviors that elephants demonstrate when they sense seismic cues. They pause and shift their weight toward their forelimbs, which places their front legs directly below their ears (Bouley et al. 2007). This allows the vibrations to travel via their bones up their leg and shoulder, into the middle ear canal (O'Connell-Rodwell 2007). Once they have pinpointed the origin of the signal, they will move to face in that direction, maintaining their weight on their front feet. They will then lift one of their rear feet, placing the front-most part of it back on the ground and rocking it back and forth from the front to the back (Bouley et al. 2007). They will often lift one of their front feet in order to triangulate the source of the signal more accurately (O'Connell-Rodwell 2007).

The pattern of rocking their foot forward and backward on the ground is believed to be associated with the pacinian corpuscles (PCs) that have been found in high densities on the most anterior and posterior regions of their foot (Bouley et al. 2007). PCs are pressure receptors that are incredibly sensitive. They occur in high densities in the fingertips of humans, allowing for the perception of minute sensations (O'Connell-Rodwell 2007). PCs likely play an important role in the interpretation and conduction of seismic signals received by elephants (Bouley et al. 2007).

When producing sound waves, elephants are able to take advantage of two possible vocal paths, each of which creates different sounds signifying different meanings. Vocalizations can be emitted either orally, through the mouth, or nasally, through the trunk (Stoeger et al. 2012). In a study examining these two vocal paths, they found that 115 rumbles were nasally emitted and 52 sources from their mouths. They found that the type of call appeared dependent on the context, with contact calls being mostly nasal and bonding situations eliciting oral calls (Stoeger et al. 2012).

Elephants have vocal tracts that are unique from all other mammals for two reasons: elephants are large animals and they have uniquely

long noses that are external from their skull, allowing for increased flexibility in the production of sound (Soltis 2010). Formant frequency is dependent on the length and shape of the individual's vocal tract. Longer tracts allow for the formation of lower frequencies (Stoeger et al. 2012). Analysis of different vocalizations yielded two approximate tract lengths: 2 m for nasal vocalizations and 0.7 m for those emitted orally (Stoeger et al. 2012). Estimates using measurements of the mandible yielded similar results with the oral tract measuring 0.75 m and the nasal tract totaling to approximately 2.5 m (Soltis 2010). Further analysis of male rumbles placed their vocal tract lengths understandably longer at 3.21 m for individuals older than 25 years (Stoeger and Baotic 2016).

There are a number of physiological adaptations elephants have for producing such low-frequency calls, the first of which is their large diaphragm (O'Connell-Rodwell 2007). Elephants also have a unique hyoid structure that is composed of five bones, rather than the normal nine that is seen in other mammals. Their hyoid structure is also separated into two sections which, combined with the fewer number of bones, allows for greater flexibility of their larynx. This is believed to contribute to their production of low-frequency sounds (Langbauer 2000; Soltis 2010).

Vocalizations result from the vibration of vocal folds in the larynx. The fundamental frequencies of different calls are determined by the rate of vibration. The sound waves are filtered as they propagate through the supra-laryngeal tract, with different vocalizations resulting from those shaped by the oral cavity versus the nasal passage (Soltis 2010; Stoeger and Baotic 2016).

Elephants' ability to successfully propagate low-frequency vocalizations is meaningless without also having the necessary anatomy to receive such signals. Their low-frequency hearing abilities are the best on any animal tested thus far and are at least ten times better than that of humans. It is believed that larger hearing anatomy may lend itself to better low-frequency detection (Soltis 2010). In addition to having large external ears and anatomy scaled to their

size, elephants also have a unique muscle surrounding the external opening of the ear (O'Connell-Rodwell 2007). This muscle functions like a sphincter and can occlude the opening of the ear. This may serve as a type of filter on the information they receive, allowing them to detect more subtle signals in their environment (O'Connell-Rodwell 2007).

## Conclusion

The complexity of elephant communication reflects the social complexity of the species. Specific physiological adaptations have allowed elephants to develop the ability to communicate over several kilometers, coordinating the movements of individuals both within and between family groups. Additionally, specific calls that signal information about the individual's identity and their physiological state have proven to be crucial for the reproductive success of the species. The complexities of the different types of calls, including those specific to males and juveniles, serve important functions that ensure the continued propagation of the species even in the harshest of environments.

## Proboscidea Diet

Barbara Toddes

Nutrition Program Director, Philadelphia Zoo,  
Philadelphia, PA, USA

## Introduction

Within the order Proboscidea, there are only two living species, the Asian elephant (*Elephas maximus*) and the African savanna elephant (*Loxodonta africana*). Both species of elephants are intermediate feeders with a preference for woody vegetation (browse), but research has shown that both species were once grazers and are in a transition back to browsing (Cerling et al. 1999). As with many animals, elephants are opportunistic foragers and will eat different foods based on availability. Human encroachment and farming in historical elephant ranges have brought the animals into direct conflict with human – competing for limited natural resources.

## What Wild Elephants Eat

A 7-year study of wild Asian elephants feeding behaviors revealed that the animals in Rajaji National Park consume a diet of 50 plant species

which varied through the year with the season. Tree species comprised nearly 74% of their diet, while grass and shrubs only 14% and 8%, respectively – grass and shrubs are predominantly consumed in the early part of the dry season (Joshi and Singh 2008). Similarly, a 2-year study at the Kuldiha Wildlife Sanctuary in Odisha revealed that the animals in the sanctuary fed on 71 different species of plants, with tree species comprising 56% of the diet, shrubs 20%, herbs 14%, and climbers 10%. Again, what the animals consumed was highly opportunistic and depended on the season (Mohapatra et al. 2013).

In Kruger National Park, African elephants consume ~ 35% of their diet in the form of grasses. A study published in 2006 revealed that the diet of animals in the northern part of the park included more grass during the dry season (~40% of the diet) compared to their southern counterparts who consume only about 10% of their diet in the form of grass during the dry season. However, during the wet season, elephants in both the northern and southern part of the park consume similar amounts of grass (~ 50%). Researchers believe the reason for the high intake of grass during the dry season for the northern animals is the type of browse that grows in that area of the park during the dry season is primarily *Colophospermum mopane* (Codron et al. 2006). This tree generates secondary metabolites which deter herbivory and is likely why the elephants avoid it (Colgan et al. 2015).

## Digestive Morphology

Both species of elephants are monogastric. The digestive tract is similar to that of a horse; elephants do not have a gallbladder, and they rely on hindgut fermentation to extract their nutrients. From mouth to anus, the digestive tract consists of the mouth, pharynx, esophagus, stomach, small and large intestine, cecum, rectum, and anus. The molar teeth, tongue, salivary gland, liver, and pancreas are accessory organs that complete the system. Interestingly, Asian elephants have a longer intestinal tract than their African counterparts. They also have a longer rate of food passage and can extract more nutrients from their food than

African elephants (Clauss et al. 2007). However, both species of elephants differ in their digestive physiology from other ungulate species. In comparison to other herbivores, they have a much shorter digestive tract, and their large and small intestine are almost equal lengths (Clauss et al. 2003b; Loehlein et al. 2003).

All mammalian herbivores depend on the fermentation of plant cell walls by gastrointestinal bacteria. Within the body size range usually studied, the efficacy of this fermentation is directly correlated to fermentation time, i.e., to passage rates. However, elephants deviate from this – they do not have long ingesta passage rates and achieve only comparatively low nutrient extraction compared to foregut fermenters. Clauss and colleagues hypothesize that abdominal space is a limiting factor for body mass; thus herbivores can only achieve great body mass with a gastrointestinal design that allows for a faster rate of ingesta passage and is the reason why elephants are hindgut fermenters and many extinct large herbivores are also believed to have been hindgut fermenters (Clauss et al. 2003a).

## In Captivity

Captive elephants tend to be much heavier than their wild counterparts (Veasey 2006). Historically, this has been largely because they consume foods with a much higher nutrient density and have a lower activity level than wild elephants (Marcus Clauss et al. 2007; Veasey 2006). Captive elephant management has changed dramatically over the past 20 years. Zoos accredited by the American Association of Zoos & Aquariums (AZA) must meet very strict housing and management requirements (“AZA Standards for Elephant Management and Care,” March 2011, April 2012). Exercise, body condition evaluation, as well as diet review and modification are required of all AZA institutions housing elephants.

Zoos and researchers are developing a number of techniques and tools to help better access animal condition, maintain healthy body weights, and ensure gastrointestinal (GI) health. Body condition scores validated through

ultrasound have created a useful tool for captive elephant management (Morfeld et al. 2014). Additionally, studies that evaluate the fecal microflora are helping animal managers better understand how the animals break down food components and identify important “healthy” bacteria within the elephant GI (Güllert et al. 2016; Ilmberger et al. 2014).

The typical captive elephant diet will include a large amount of browse, grass hay, and an elephant supplement pellet designed to ensure the animals receive adequate vitamin and minerals that may be lacking in the browse or hay. Until recently, zoos also offered large amounts of produce – this practice has been abandoned in the daily diet by most zoos as produce is not normally consumed by wild elephants and the gut has not evolved to accommodate it in large amounts.

## Conclusion

Asian elephants are listed as endangered, and their wild populations are continuing to decline (“*Elephas maximus* (Asian elephant, Indian elephant),” n.d.); African elephants are listed as vulnerable (“*Loxodonta africana* (African elephant),” n.d.). Both species live in severely fragmented habitats, are in conflict with humans for land, and poached for their ivory. Understanding their foraging strategies, dietary needs, and nutrient utilization will help identify the resources needed for wild elephants as well as ensure appropriate care in captivity.

[Elephant locomotion](#); [Proboscidea gaits](#)

## Definition

Movement used by elephants (the only extant members of the Order Proboscidea) to traverse the environment.

The elephant and its extinct relatives belong to the Order Proboscidea, a division of Afrotheria (one of the major clades of placental mammals that includes golden moles, elephant shrews,

tenrecs, aardvarks, hyraxes, elephants, and sea cows). At its peak diversity, Proboscidea contained up to 175 species and subspecies, classified into 42 genera and 10 families. After the woolly mammoth (*Mammuthus primigenius*) became extinct, only three living species under the family Elephantidae remain. The three existing species are the African forest elephant (*Loxodonta cyclotis*), the African bush elephant (*Loxodonta africana*), and the Asian elephant (*Elephas maximus*). There are three subspecies of the Asian elephant: *E. m. sumatranus*, *E. m. indicus*, and *E. m. maximus* (Shoshani and Tassy 2005). Of these remaining species, the *Loxodonta* are geographically restricted to Africa, while the *Elephas* has migrated out of Africa and into more temperate regions, such as Asia and Europe. The decline of the Order Proboscidea as well as an increase in the distribution of C4 plants (grasses and hedges), has resulted in the adaptive radiations of elephants (Sanders 2010). Today, elephants are the largest living terrestrial animals. However, their exceptional dimensions come with both advantages, such as a decreased energetic cost of locomotion, and disadvantages, such as a greater fragility as compared to smaller animals (Genin et al. 2010).

## Quadrupedal Gait Mechanics

Elephant locomotion is classified as quadrupedal locomotion, whereby four limbs support and propel the body. Despite this classification, the elephant's gait is somewhat atypical of the classic quadrupedal gait. In most quadrupeds, there is a transition speed between the pendular mechanism of the walking gait and the bouncing mechanism of the running gait, which influences variables such as the footfall pattern, the limb phase (the time interval between two sequential limb touchdowns), and the duty factor (the fraction of a stride in which a limb is in contact with the ground) (Genin et al. 2010). Unlike other quadrupeds, elephants do not demonstrate a defined gait transition. In other words, they do not have a clear shift from a walking phase to a trot or a gallop. As they increase speed, their

**Proboscidea Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hind limb duty factor collected during quadrupedal walking in elephants ( $n = \text{two species}$ )

step length and step frequency also increase. However, an elephant’s gait remains within the boundaries of a lateral sequence footfall pattern (with lateral couplets or single-foot) regardless of their speed. This means, the elephant’s left hind limb is always followed by its left forelimb while its right hind limb is always followed by its right forelimb (Fig. 1). This is why elephants are considered to have a smooth gait transition. Furthermore, as an elephant’s forelimb footfalls increase linearly with speed, the phasing becomes more evenly spaced in time, resulting in lateral couplets at slower speeds and a true single-foot at higher speeds. Because the elephant’s forelimb and hind limb footfalls are evenly spaced in time, its gait can be described as symmetrical (Hutchinson 2006).

An important question is whether elephants can run? Typically, definitions of running mechanics are based on the interchange between potential energy (PE) and kinetic energy (KE). During running, animals continuously recover the PE stored in tendons and muscles into bouncing KE. During walking, animals convert PE to KE as they step forward (Knight 2010). Furthermore, the transition into the running gait is usually associated with a whole-body aerial phase (period

in which no limbs are in contact with the ground). However, elephants never achieve this full aerial phase. At speeds over  $\sim 2 \text{ m s}^{-1}$ , only the elephant’s hind limbs illustrate an aerial phase with bouncing while the forelimbs maintain a straighter morphology (Ren et al. 2008). Even though elephants may appear to be running at high speeds, Hutchinson (2006) has shown that elephants’ front limbs walk and their hind limbs trot during fast locomotion. Therefore, in a classical sense, elephants do not display a running gait.

Despite the numerous differences, elephants demonstrate some similarities to other quadrupeds. For example, like other quadrupeds, when an elephant increases its speed, it does so by initially increasing its stride frequency as opposed to increasing its stride length. An increased stride frequency results in an increased joint angular velocity (the rate of flexion and extension of a joint). However, when the elephant’s speed begins to reach its near-maximal threshold, the elephant relies on highly increased joint rotation in an attempt to generate longer strides. Therefore as speed approaches near-maximal values ( $> 5\text{--}6 \text{ ms}^{-1}$ ), elephants achieve near-maximal stride frequency, primarily by increasing stride length (Huchinson 2006).

Genin et al. (2010) used a force platform to measure ground reaction forces (forces exerted by the ground on the limbs) under an elephant during its gait cycle. Measurements were taken over a wide speed range ( $0.38 \text{ m s}^{-1}$  to  $4.97 \text{ m s}^{-1}$ ), and it was found that hind limb and forelimb loading were divided into rigid and compliant parts at speeds over  $2.8 \text{ m s}^{-1}$ . During hind limb loading, the elephant’s contralateral forelimb was grounded, and the vertical ground reaction force increased (Fig. 2). However, the elephant’s center of mass (COM) vertical displacement remained relatively constant (Fig. 2). This shows that the hind limb and the contralateral forelimb act as a rigid, noncompliant system. This differs from forelimb loading, where the elephant’s ipsilateral hind limb was grounded, and the vertical ground reaction force increased, while the vertical displacement of the COM decreased. This indicates that the forelimb and the ipsilateral hind limb act

**Proboscidea Locomotion, Fig. 2** Left: Typical curve of vertical ground reaction force ( $F_v$ ) and vertical displacement of the center of mass ( $S_v$ ) over one-step cycle as a function of time. The letters indicate: (a) hind limb

touchdown, (b) hind limb maximal load, (c) forelimb touchdown, and (d) forelimb loading. Hind limb loading (from a to b) and forelimb loading (from c to d). Data from Genin et al. (2010)

as a compliant bouncing system, similar to a spring-mass system (Genin et al. 2010).

### Comparison Between Species

The African and Asian elephants have strong kinematic similarities as they both achieve a maximum speed of slightly less than  $7 \text{ m s}^{-1}$  (Hutchinson 2006). The individual limb bone development is also similar, but the two species differ in their mechanical adaptations, indicating differences in evolutionary adaptations. The limb bones of the Asian elephant are better for adjusting to peak muscular forces than the limb bones of the African elephant. During high speeds, Asian elephants generate muscular forces that exceed their body weight, resulting in a complex bending/torsion and elastic bone stress that allows for large levels of limb compliance. Also, the Asian elephant can maintain higher speeds than that of the African elephant (Kokshenev and Christiansen 2010). On the other hand, the limb bones of African elephants can overcome axial compression through a more energetically

efficient design. Their bones avoid bending/torsion, resulting in a shorter stride length and higher stride frequency than Asian elephants during increased speeds. Regardless of these differences, both are limited in near-maximal stride length and near-maximal speed as compared to other mammals, due to a negative limb bone compliance gradient (Hutchinson 2006).

Another factor that influences locomotion is the size of the elephant. Larger elephants are not capable of reaching the same locomotive intensity as smaller elephants. At increased speeds, larger elephants prefer walking, which relies less on the compliance of bone tissue. Smaller elephants display minimal duty factors and utilize a near-maximal stride length and frequency. The maximum speed of elephants usually peaks at a young age as a result of the environmental pressure to escape predation, a factor that does not have as great of an impact on older elephants. Consequently, older elephants do not have a great need for higher speed capacity. Nevertheless, the gait transition is relatively smooth in all elephants regardless of their size and all have compliant hind limb function at high speeds (Hutchinson 2006).

## Energetics and Migration

Energy consumption, also known as fuel-economy, during animal locomotion are assumed to be driven by the time it takes to apply forces to the ground by each foot and the force that muscles must generate to support the body weight. Movement from rest requires a significant amount of energy, especially as the load increases (Kram and Taylor 1990). Of note for African elephants is their significant body weight (~6000 kg), which is supported by four pillar-like legs. While it was previously theorized that elephants have a low fuel-economy, Langman et al. (1995) has shown that this is not the case. Evolution has favored longer legs in elephants to allow for longer stride length. This allows them to move at slower speeds, while still covering a long distance with each stride. Slower moving muscles help reduce the force generation and thereby increase the fuel-economy. The fuel cost of the African elephant has been estimated to be 1/40 that of a 7 g pygmy mouse due to these biomechanical adaptations. Net cost of transport in elephants, estimated by oxygen consumption during walking, follows a U-shaped curve (Fig. 3). The net cost of transport increases in two conditions: (1) movement from rest (0–0.99 m/sec), to overcome inertia and (2) movement beyond 1 m/sec, in accordance with speed. The lowest net cost of transport ( $0.78 \text{ J kg}^{-1} \text{ m}^{-1}$ ) is at 1 m/sec, which is approximately the walking speed of humans. The consequent high-fuel economy

allows the elephant to traverse long distances, especially during seasonal mass migrations. Migrations involve traversing 480–640 km, while maintaining a constant speed for 3–4 h or ~16 km (Langman et al. 1995). The African elephant is known to migrate long distances at a leisurely pace and eventually dwell in open environments. The Asian elephant is found in more heterogeneous, forested environments, and partakes in fewer or no seasonal migrations (Hutchinson 2006).

## Additional Locomotor Activities

In addition to the gait patterns discussed, African elephants can also perform aquatic locomotion to travel from island to island during mainland food shortages. They can travel at a maximum speed of approximately 2.70 km/h and a maximum distance of 48 km. Their locomotion can be described as a “lunging, porpoise-like fashion,” which utilizes a three-step repeating sequence. First, the elephant takes a deep breath by exposing its trunk, top of its head, and half of its body. Second, the elephant submerges its body and begins its first stride. The trunk is kept  $45^\circ$  above water, acting as a snorkel, to assist with breathing. Finally, the elephant sweeps its trunk downward to propel itself forward, and the sequence repeats (Johnson 1980).

### Proboscidea

## Influence on Bioinspired Robotics

As described above, the elephant's trunk assists the elephant with moving through aquatic environments. The long and boneless trunk also allows the large terrestrial mammal to grasp and squeeze food particles together, create a pile, and then lift the particles to its mouth. Furthermore, the trunk is capable of curling around nonfood objects and elevating them (Wu et al. 2018). The ability of the trunk to grasp and manipulate objects has proven to be influential for soft robotics. Soft robotics is a field that generates robots using compliant materials inspired by those found in living systems. The dexterity and functionality of these innovative creations make them suitable for use by humans for “wearable, surgical, and collaborative robotics” (Mitchell et al. 2019). One such creation is the Soft Poly-Limb (SPL). The SPL is a fluid-driven and wearable system that is analogous to having an additional limb. Similar to the elephant trunk, the SPL helps the wearer surround, suction, and grasp an object up to 2.35 times greater than its own weight. This bioinspired creation can provide mobile assistance to both healthy and impaired users (Nguyen et al. 2019).

## Conclusion

This entry presents an overview of the elephant's major modes of locomotion. Elephants follow a lateral sequence footfall pattern regardless of speed. To shift to higher speeds, the elephant starts off by increasing its stride frequency and then shifts to increasing its stride length. Elephants are not capable of true running because they never achieve a whole-body aerial phase. Furthermore, despite their large dimensions, elephants can perform aquatic locomotion, a form of locomotion that has not been commonly attributed to them. The distinct locomotive behaviors of elephants make them an interesting class of mammals to study. Further knowledge of their gait sequences and trunk mechanics can continue to produce advances for the scientific community.

## Definition

General structure of elephants, the only extant members of the order Proboscidea.

## Introduction

More than 160 Proboscidean species have existed over time (Sukumar 2003); however, only three remain (Payne 2003). The three extant members of the Proboscidea order are as follows: the Asian Elephant (*Elephas maximus*), the African Savannah Elephant (*Loxodonta africana*), and the African Forest Elephant (*Loxodonta cyclotis*) (de Silva 2010). Elephants are the largest terrestrial animals on the planet, and as such they have adapted a unique morphology to support such size. Elephants' closest relatives are sirenians, hyraxes, and aardvarks, the closest of these being the Sirenians (Sukumar 2003). Proboscidea originated approximately 60 million years ago, during the late Paleocene Epoch; however, only the three extant species remained by the end of the Pleistocene, during which over half of large mammals faced extinction (Sukumar 2003). Proboscideans went through extreme dwarfism and changes of shape before an overall increase in body size around 10,000 years ago (Sukumar 2003). Though Proboscidea fossils have been found on every continent except for Australia and Antarctica (Sukumar 2003), *Loxodonta* and *Elephas* share their origins in Africa during the late Miocene (Todd 2010). It is believed *Elephas*

left Africa during the last ice age in the Northern Hemisphere, roughly 35,000 years ago (Spinage 1994).

## Skeletal

Elephants are the archetype of the graviportal animals, or animals with large body size and long, columnar limbs (Hutchinson et al. 2006). African elephant cows average a height of 2.7 m tall and a weight of 2.5 tons; while African bulls average a height of just over 3 m tall, and a weight of 5.5 tons (Spinage 1994). Asian elephant cows average a height of 2.35 m tall and a weight of up to 2.54 tons; while Asian bulls average a height of 2.7 m and a weight of up to 4.16 tons (Spinage 1994). Elephants may be able to grow throughout the majority of their lives (Smuts and Bezuidenhout 1994). The tails of elephants can measure up to 1.5 m in length (Spinage 1994).

The femur is the longest bone in the elephant skeleton, capable of measuring over 1 m long (Smuts and Bezuidenhout 1994). An elephant's skeleton weighs roughly 16.5% of its total living weight (Spinage 1994). According to Gary West, elephant skeletons consist of over 200 bones, though Asian and African elephants differ slightly in structure; Asian elephants typically have 19 rib pairs and 33 caudal vertebra, whereas African elephants have 21 rib pairs and 26 caudal vertebra (Fowler and Mikota 2006). Elephants support about 60% of their weight on their fore-limbs (Spinage 1994). The bones that make up elephant limbs are very dense and have no bone marrow cavity, which make the bones stronger and more able to carry such great weight (Fowler and Mikota 2006).

## Brain

Animals with large brain size relative to body size exhibit heightened ability process and apply complex inputs (Garstang 2015). With weights ranging from 3.6 to 6.5 kg, elephants have the heaviest brains of any land mammal (Fowler and Mikota 2006). The heaviest elephant brain ever recorded

was 9.0 kg (Garstang 2015). The elephant brain is well-developed, and similarities between human and elephant brains emphasize a capability for higher thinking (Garstang 2015). Within the elephant brain, the cerebellum accounts for 18.6% of the entire brain, a relatively large proportion compared to humans (10.3%); this large cerebellum helps coordinate movements, locomotion, and posture and helps coordinate the complex movements associated with moving the trunk (Garstang 2015).

Elephants have large temporal lobes, associated with memory and learning, and large olfactory lobes, exhibiting a dependence on memory and olfaction (Fowler and Mikota 2006). The large temporal lobe is likely associated with the ability to communicate via infrasonic methods (Garstang 2015). The relative weight of both the temporal lobes and the cerebral cortex are the greatest of all mammals (Garstang 2015).

Elephants also have an abnormally large hippocampus, responsible for memory, emotion, spatial memory (Bohbot 2015), and for identifying individuals by way of social and chemical memory (Garstang 2015). Elephants' well-developed hippocampal structures allow for advanced processing ability, and the experimental evidence of Polansky et al. suggests elephants can recall the locations of other individuals relative to their own locations (Polansky et al. 2015).

## Reproduction

Temporal glands are unique to elephants and are present in all three species and in both males and females (Fowler and Mikota 2006). The female reproductive tract is about 3 m long, making it the longest of all land mammals; the vestibule, or the urogenital canal, accounts for a third of this length at over 1 m (Hildebrandt et al. 2010). The female reproductive tract consists of two ovaries, Fallopian tubes, bicornuate uterus, vagina, and vulva; the most unique features are the 1-m long urogenital canal and the pronounced clitoris (Sukumar 2003). The vagina can measure up to 50 cm in length and is internally marked by longitudinal folds (Hildebrandt et al. 2010).

The hymen ruptures during a cow's first delivery, which separates elephants from most mammals, whose hymens rupture during copulation (Hildebrandt et al. 2010). Birth weights range from 100 kg to 120 kg, and cows carry their calves for 22 months (Spinage 1994).

The bull's penis has an S-shaped structure when erect, allowing it to hook into the forward-directed vagina (Sukumar 2003). Bull elephants lack cooling mechanisms for their testes, unlike other mammals (Spinage 1994). Bull testes are located within the abdomen (Sukumar 2003), and near the kidneys (Spinage 1994). Testes can weigh up to three kilograms each (Spinage 1994).

## Integument System

Elephant skin color is usually gray, but may become brown or reddish depending on the substrate used for bathing (Fowler and Mikota 2006). Skin can be up to 3.2 cm thick on their backs and as thin as 1.8 mm on their ears (Fowler and Mikota 2006). Elephant skin contains complex polygonal columns, which act as studs in a wall, strengthening certain areas of the skin, particularly the forehead (Fowler and Mikota 2006). The skin on the trunk, breast, legs, ears, and groin are the thinnest areas (Spinage 1994). Elephant skin may be the largest sensory organ of the elephant (Fowler and Mikota 2006). Asian elephants are typically hairier than the African species, and fetal and newborn elephants are hairier than adult elephants (Fowler and Mikota 2006).

## Gastrointestinal

The elephant digestive tract begins with the mouth (which includes the trunk), and then continues into the pharynx, esophagus, stomach, small intestine, large intestine, cecum, rectum, and finally, the anus (Greene et al. 2019). Within the mouth, elephant tongues are attached to the floors of their mouths, and though they cannot protrude, they can fold in center; these tongues can weigh as much as 12 kg (Greene et al. 2019). Elephants lack a gallbladder, as do equids (Greene et al.

2019). The gastrointestinal tract of the elephant is approximately three times its body length, which is relatively short when compared to other herbivores; for example, the gastrointestinal tract of the horse is nearly 12 times its body length (Greene et al. 2019).

Similar to rabbits and horses, elephants are hind-gut fermenters, meaning the first significant fermentation site in the digestive tract is the cecum, and the main digestive area is the colon (Fowler and Mikota 2006). This inefficient method of digestion means that elephant must consume large amounts of low-quality forage in short amounts of time; therefore, wild elephants spend between 16 and 20 h eating each day (Fowler and Mikota 2006). The elephant cecum accounts for approximately 12% of its body weight (Greene et al. 2019). This means that the cecum of 10,000 pound elephant would weigh 1,200 pounds! Asian elephants are capable of digesting between 40% and 50% of their diet, whereas African elephants may digest as little as 22% (Greene et al. 2019). Elephants may defecate between 15 and 12 times daily, with average defecation weight of approximately 10 kg (Fowler and Mikota 2006).

## Elephant Trunk Morphology

The elephant trunk has quite the interesting anatomy as it is often perceived as a hand or nose, but on the inside appears as a tongue. One of the most commonly cited elephant facts in literature, media, and elephant outreach is *an elephant trunk has 40,000 muscles, or 150,000 muscle fibers* (Spinage 1997). However, this was only an estimation made by a French Naturalist Georges Cuvier at the beginning of the nineteenth century (Cuvier 1806). There is no current evidence of a proper estimation of the number of muscles inside of a trunk. Elephants have developed trunks to increase bite volume and bite mass. This allows them to increase their food consumption rate (Pretorius et al. 2016). The lack of any bone inside of the elephant trunk makes it very similar to that of octopus arms and tongues; these

three examples are known as muscular hydrostats (Kier and Smith 1985).

Three muscle types are found along the trunk including radial muscles located around the nasal passageways, longitudinal muscles located between the radial muscles and skin, and finally oblique muscles located on the ventral side of the trunk below the radial muscles (Kier and Smith 1985). These muscles allow the trunk to elongate, bend, and twist (Kier and Smith 1985). The two oblique muscles allow the trunk to move to the left or right. The most detailed account of elephant trunk muscle types is shown in the original 1909 monograph on the elephant head by JV Boas and Simon Paulli (Boas 1908). Based on cross-sectional observations of elephant trunks, octopi's arms, and various tongues, Kier (Kier and Smith 1985) posited that muscular hydrostats should satisfy constant volume when moving. It has been approximated these muscles contain a modulus of elasticity of 938 kPa through weight lifting experiments (Wilson et al. 1991).

On the outside of the muscle there is a thick layer of elephant skin that appears to be wrinkled. The wrinkled skin on the elephant functions different than that of the skin on the body, which assists with heat regulation and repelling insects (Martins et al. 2018). The skin of the elephant trunk is comprised of wrinkles near the tip that turn into folds as they approach the base of the elephant trunk. Both the skin on the elephant's body and trunk does not contain sweat glands (Spearman 1970). This is one of the reasons the elephant is constantly spraying itself with water and throwing dirt on their body for aiding thermoregulation.

Underneath the wrinkled skin of the elephant trunk are hairs, specifically vibrissal hairs (Spearman 1970). These vibrissal hairs are commonly referred to as whiskers, and they are sensing or tactile hairs (Prescott et al. 2011). It is unknown currently what the use and function of the whiskers along the elephant trunk are; however, there is a large cluster of the hairs near the tip of the elephant trunk.

Their prehensile trunks can pick up objects as small as a peanut (Onondera and Hicks 1999) and manipulate tools (Hart et al. 2008), demonstrating precise motor control. Anatomically, elephants

have underdeveloped occipital lobes compared to their olfactory and temporal lobes (Shoshani et al. 2006), which may indicate that they rely less on vision to accomplish motor tasks. Elephants can detect TNT with better accuracy than most trained bomb detection dogs (Miller et al. 2015). In fact, their ability to reach for food items may be impaired if the trunk cannot be used to sense olfactory cues (Foerder et al. 2011). However, elephants likely still utilize vision to accomplish reaching. Their retinas have a concentration of retinal ganglion cells in the upper temporal region, which corresponds to the area of the visual field where the trunk moves (Stone and Halasz 1989). Additionally, they can accurately discriminate visual cues that are less than a degree in width of the visual field (Shyan-Norwalt et al. 2010).

## Ears

African elephant ears are large, positioned above the neck, and shaped similarly to the continent of Africa, while Asian elephant ears are significantly smaller, positioned below the neck, and generally trapezoidal in shape (Fowler and Mikota 2006). Ears are supported by "lattice-like" areas of cartilage and they are used for more than just hearing; they are used for thermoregulation, balance, and communication (Fowler and Mikota 2006). Although they struggle with high-frequency sounds, elephants can hear low-frequency sounds more effectively than any other animal (Fowler and Mikota 2006). Utilizing infrasonic sounds, elephants can communicate over great distances (Fowler and Mikota 2006).

In all three elephant species, ears maintain a high surface area to volume ratio (Wright 1984). Elephant ears are important in thermoregulation because by flapping their ears, African elephants can increase up to 20% surface area for heat dissipation, and Asian elephants can increase their surface area by up to 10% (Fowler and Mikota 2006). Ears have a significant and extensive vascular supply, and are fanned often in warm temperatures (Wright 1984). Arteries in elephant ears constrict under cool weather conditions, and elephants tuck their ears against their sides to maintain body temperature (Wright 1984).

## Feet

Elephants are the largest land mammals, and their feet are uniquely fitted to accommodate massive weight (Weissengruber et al. 2006). Movement allows elephants to circulate blood from their feet back to the heart (Fowler and Mikota 2006). The bones of the foot lay on a unique fatty pad, or cushion, that aids in shock absorption and allows elephants to walk without stomping (Spinage 1994). The cushion is composed of sheets and strands of connective tissue that form large and small compartments filled with adipose tissue (Weissengruber et al. 2006). The cushion spreads when weight is upon it, allowing for the hefty load. It also reduces suction when walking through deep mud because the entire circumference of the foot shrinks as the elephant lifts its foot (Spinage 1994). In addition to weight distribution, the elephant foot's cushion may store or absorb mechanical force (Weissengruber et al. 2006).

The bones of an elephant's foot form an arch, similar to a human foot (Weissengruber et al. 2006). Each foot has five digits, though the amount of phalanges and nails vary by individual elephant (Fowler and Mikota 2006). Asian elephants typically have five nails on the front feet, and four on the rear, while African elephants typically have four on the front feet, and three on the rear (Spinage 1994). The sole of the hindfoot is smaller and more oval than the rounder front foot (Weissengruber et al. 2006).

The foot covering is composed of skin, toenails, and a cornified, though flexible sole called the slipper (Fowler and Mikota 2006). Toenails are large, relatively flat, and are embedded against the foot (Spinage 1994). Similar to humans, each elephant toenail has a cuticle, and is not weight bearing like a hoof (Fowler and Mikota 2006).

## Dentition

The enamel loops on the teeth of African Elephants are lozenge-shaped, thus the genus *Loxodonta* was named (Greene et al. 2019).

Elephant molars have a unique system of eruption and replacement (Todd 2010). Elephants go through six sets of four molars throughout their lives (Fowler and Mikota 2006). Molars are degraded and lost in sections, and replaced by new teeth which push from behind the old tooth (Fowler and Mikota 2006). Each new tooth is larger than the previous tooth, and each adult elephant molar may weigh greater than five kilograms (Fowler and Mikota 2006). Because of this unique system of replacing teeth, it is possible to approximate an elephant's age by examining its teeth and determining which set the elephant is on (Lindeque 1990).

All African elephants and male Asian elephants have prominent tusks, and female Asian elephants may have small tushes, or vestigial tusks (Fowler and Mikota 2006). Permanent tusks develop within 6–12 months of age, replacing deciduous tusks with no apparent function (Fowler and Mikota 2006). Tusks emerge from a sulcus on each side of the upper lip and are extensions of the upper second incisors (Fowler and Mikota 2006). Male tusks may grow as much as six times faster than female tusks, and all tusks average a growth rate of roughly 17 cm annually (Fowler and Mikota 2006). Elephant and hyrax tusks differ from other mammalian tusks in that their tusks develop from incisors instead of canines (Greene et al. 2019). Elephants have many functional uses for their tusks. They are used to dig for water, to strip bark from trees, to break branches, to carry heavy objects, and are used as weapons during conflicts (Fowler and Mikota 2006). As a person is right-handed or left-handed, elephants tend to be either right-tusked or left-tusked, and the dominant tusk is usually apparent in the degree of wear on the tusk (Fowler and Mikota 2006).

## Conclusion

Elephants are the largest of all land animals and as such have developed unique morphologies to support such size and intelligence. From a highly

capable brain to heavily adapted trunks and feet, elephants are truly unique.

## Proboscidea Navigation

Scott Hooper  
Zoo Atlanta, Atlanta, GA, USA

### Synonyms

[Locomotion](#); [Migration](#); [Movement](#)

### Definition

Why and how elephants move from a starting point to a target point.

### Introduction

Approximately 160 proboscidean species have populated the Earth; however, only three remain (Payne 2003). The three extant members of the Proboscidea order are as follows: the Asian Elephant (*Elephas maximus*), the African Savannah Elephant (*Loxodonta africana*), and the African Forest Elephant (*Loxodonta cyclotis*) (de Silva 2010). The demise of Proboscidea is likely due to humanity; in fact, 80% of elephant mortalities take place within a 25-mile radius of people (Roever 2013). Despite this, the three elephant species remain, largely in part due to their ability to navigate and adapt to an evolving world. Though the African species have been observed to walk further and faster than Asian elephants, it is clear that walking is critical to the health of all elephants (Mackey 2014). When moving, the pads of an elephant's foot compress and relax, allowing blood to circulate throughout the central venous system (Mackey 2014). Elephant movement has long been noted in various African and Asian cultures (Garstang et al. 2014).

### Locomotion

The largest of all terrestrial animals, elephants are the archetype of the graviportal animals, or

animals with large body size, columnar limbs, and a vertical posture (Hutchinson et al. 2006). Elephants are known for this vertical posture, which suggests their limbs have very little flexibility and their joint use is limited; however, recent studies have shown that elephant limbs are not usually vertical when supporting weight, especially while moving (Ren et al. 2008). Even while standing, joints maintain degrees of flexion (Ren et al. 2008). As elephants increase speed, they also increase flexion in their limbs, meaning leg posture is significantly different in a fast-moving elephant than in a stationary elephant, most likely because impact on stiff legs could have disastrous consequences in such large animals (Ren et al. 2008).

Elephants are efficient walkers because they are able to convert potential energy into kinetic energy and back via a mechanism similar to a pendulum, meaning muscular work is reduced (Genin et al. 2009). When moving at higher speeds, elephants utilize a bouncing mechanism of energy conversion in order to maximize efficiency (Genin et al. 2009). When moving, elephants move their feet in a lateral sequence, meaning the hind-foot of one side is always followed by the forefoot of the same side (Genin et al. 2009). Even at their highest speeds, elephants never alter their footfall pattern so that all 4 ft are off the ground in what is called an aerial phase, which is why they are unable to run in the classical sense of the word (Hutchinson et al. 2006).

Even though they cannot “run,” the fastest elephants can still move at speeds of up to 25 km/h, though only for short distances (Hutchinson et al. 2003). Elephants are able to gradually increase their speed without significantly changing the way they move their limbs (Ren et al. 2008). To increase speed, elephants increase the frequency of strides, then, when moving at higher speeds, increase stride length (Genin et al. 2009). Although it is maintained that elephants are incapable of running because they exhibit no aerial phase, their hips do exhibit a downward, then upward motion during top speeds, which suggests they are indeed running; however, more evidence is needed on the ground-

force of movement before this matter is resolved (Hutchinson et al. 2003).

## Herd Dynamics and Navigation

Togetherness is a necessity in elephants. Family or herd members spend the majority of their time together, over 80%, and they exhibit coordination in all facets: defense, raising of offspring, and locating resources (Vidya and Sukumar 2005). The matriarch is usually the oldest and most experienced female in the family and is an invaluable source of information for the location of resources (Vidya and Sukumar 2005). Although African elephants typically travel in small family groups, great precipitation events or disasters can lead to aggregations of over 100 individuals (Spinage 1994).

## Sensory Modality of Navigation

Elephants rely heavily on acoustic and olfactory methods of perceiving their environment, rather than vision (Plotnik and de Waal 2014). Elephant vision is limited past 50 m; therefore, they must rely on their other senses when navigating (Garstang 2015).

Often, elephants navigate their way to food sources by smell (Plotnik et al. 2014). Compared to most of the animal kingdom, elephant olfaction is nothing short of amazing. The African elephant genome contains the largest olfactory receptor repertoire of any species ever studied (Nimura et al. 2014). In one study on Asian elephants, individuals were able to discriminate between 24 odor pairs, with each odor only differing by one carbon molecule (Nimura et al. 2014). Elephants may even use olfactory cues from food, water, and other elephants when making migratory decisions, not only for the daily location of foods (Plotnik et al. 2014). Elephants also utilize olfaction to avoid danger. By sniffing out individual mines, Namibian elephants were observed navigating across minefields without injury (Garstang 2015). Elephants also use olfaction for mate-finding (Nimura et al. 2014).

Acoustic ability is equally important to elephant navigation. Elephants can detect low-frequency calls from distances of several kilometers and can even pick up infrasonic signals (de Silva 2010). Separate elephant herds in Namibia exhibited near-simultaneous changes in direction when rainfall occurred over 100 km away, and infrasound created by the rain system is believed to be the trigger for the changes in movement (Garstang et al. 2014). Vocalizations between individuals and herds aid elephants in finding or keeping distance between separate herds. Asian elephants have been observed to vocalize in at least 14 distinct categories that serve various spatial and social functions. Growls and rumbles are unique to individuals and are often used for locating one another or maintaining separation between other herds. Elephants also use acoustic signals for finding mates, especially in African savannah elephants (de Silva 2010).

## Brain, Memory, and Navigation

Since matriarchs lead their herds to food and water by memory, it is logical that herds with more experienced matriarchs, who maintain massive stores of spatial memory, demonstrate higher survival rates during rough periods of drought or famine (Garstang 2015). Because of excellent long-term memory, elephants are able to remember remote areas of food and water and navigate to those areas over great distances of indistinct landscapes; in fact, Namibian elephants have been observed locating oases that had not been visited for over 20 years (Garstang 2015). When switching between watering areas in Namibia, elephants move directly but not always to the closest water source, suggesting memory of resource availability at different times of the year (Polansky et al. 2015). African savannah elephants are believed to utilize spatial memory strategies to navigate their environments, which may be due to their robust hippocampal structures (Bohbot 2015).

Spatial memory is characterized by the ability to straight-line navigate to a target, even from different starting points, and is found to be

dependent on the hippocampus (Bohbot 2015). Elephants take direct trajectories to water holes, which is indicative of the spatial memory strategies used by humans to navigate (Bohbot 2015). Spatial memory may be the major mechanism elephants use to navigate their habitats, especially when locating sources of water (Polansky et al. 2015). This means that elephants can form and follow cognitive maps and then use those maps to take direct routes to specific locations (Bohbot 2015). Cognitive maps are flexible collections of spatial information that can be manipulated so that elephants can discover novel ways to a certain destination, which is different from a rigid, stimulus-driven route that cannot be altered (Bohbot 2015).

Patterns of elephant movement have been detected monthly, seasonally, annually, and over multiyear periods, meaning elephants can pick up on vegetation patterns that span years (Birkett et al. 2012). In India, Asian elephants use well-worn paths in search of food (Spinage 1994). Asian elephants are also capable of adjusting these routes and migration patterns to adapt to human encroachment (Johnsingh and Williams 1999). For example, Asian elephants in India stopped using a centuries-old migration corridor within 10 years of a railroad being built within the corridor (Johnsingh and Williams 1999).

## Home Range

African Savannah elephants inhabit East and Southern African Savannas, and one population exists in the desert region of Namibia; African Forest elephants inhabit equatorial rainforests in Western and Central Africa; and Asian elephants live in forests and forest edges of India, Southeast Asia, and Island Asia (Payne 2003). Though habitats differ across the three species, water, tree cover, slope, and human presence are important factors in habitat selection for all elephants (Roever 2013). Elephant home ranges can stretch anywhere from 200 km<sup>2</sup> to 11,000 km<sup>2</sup> (Mackey 2014). Typical herd behavior involves remaining in one part of the home range for up to 3 days before moving onto another spot (Spinage 1994).

Elephant ranges shrink with increased elevation (Bohrer et al. 2014). Home range changes seasonally in many elephants depending on the availability of water. Most elephants return continually to the same dry season home range in proximity to a permanent water source. These areas become overused in the dry season (Spinage 1994). Desert-dwelling Savannah elephants have significantly larger home ranges during the wet seasons than during dry seasons, due to water availability (Bohrer et al. 2014). Radio-collared elephants have been noted to stray over 40 km away from permanent water sources in the wet season, but no more than 16 km away during the dry season (Spinage 1994). It is important to note that changes in elephant home ranges also occur because of proximity to people. Fifty-eight percent of the Savannah elephant population lives in Southern Africa, and 72% of these elephants' ranges exist beyond protected spaces (Roever 2013).

## Migration

It was once believed that all elephants must partake in long, seasonal migrations to satisfy their feeding needs. There is even one recorded observation of approximately 2000 elephants migrating over 100 km to the coast (Spinage 1994). Though elephants surely have migrated long distances and in large groups, this is not true of all elephants. Asian elephants have not been known to conduct large migrations (de Silva 2010). The movements of African savannah elephants are heavily influenced by precipitation, temperature, and primary productivity in the area (Birkett et al. 2012). In both Asia and Africa, fires influence elephant movement by forcing them to leave burning areas, though they usually return to the area following the flush of green vegetation that occurs after fires (Spinage 1994). Elephants migrate quickly in response to both large-scale and small-scale precipitation events that affect the availability of food and water (Bohrer et al. 2014). These movements are usually performed within family units; however, during large-scale precipitation events, aggregations of up to 1000 individuals have

been observed. Elephants do not migrate as birds do, based on some predetermined signal; instead, they follow foliage and rainfall, which may bring multiple herds to move in the same direction (Spinage 1994).

In favorable conditions, elephants are less likely to leave their home ranges, while elephants in unfavorable year-round climates undergo seasonal migrations. Thus, the average distances traveled by elephants vary greatly (Spinage 1994). Aside from seasonal movements, monthly, annual, and multiyear patterns have been detected in elephants (Birkett et al. 2012). The average straight-line distance of these migrations is roughly 73 km, with a total distance of 90 km. Distance traveled during migration depends on the home range. For example, the Gourma elephants of Mali travel 800 km in a seasonal round trip, crossing up to 80 km daily (Spinage 1994).

### Precipitation and Availability of Food

Elephants spend between 60% and 80% of their day foraging, or searching for food (Mackey 2014). In African savannahs, vegetation changes with seasonal changes in rainfall; thus, rainfall patterns significantly affect the movements of savannah elephants because they shift their patterns to match the availability of food (Birkett et al. 2012). Elephants have been known to abruptly travel between 30 and 50 km in several days to areas of plentiful grazing following large-scale precipitation events (Spinage 1994). In fact, elephants are so sensitive to rainfall that separate elephant herds in Namibia exhibited nearly simultaneous changes in movement when rainfall was occurring over 100 km away (Garstang et al. 2014).

Elephants exhibit seasonal changes in behavior, according to rainfall patterns. African savannah elephants increase their speed of movement during the wet season. Then, they decrease movement at the end of the wet season and the beginning of the dry season, in preparation for the changes in precipitation and availability of foliage (Birkett et al. 2012). In the dry season, movements are restricted to areas within a certain proximity of

a permanent water source. Elephants may not move farther than three kilometers away from a water source during these times (Spinage 1994).

In terms of elevation, elephants tend to move up and down in accordance with the growth and decline of vegetation. When habitats are green and food is plentiful, elephants occupy lower elevations; however, they return to higher areas with evergreen forests when food starts to dry up (Bohrer et al. 2014). Elephants that inhabit flood-plains exhibit not only seasonal but daily patterns of movement, particularly in the dry season. They have been observed to stay in wooded areas in the day, and venture into the flood-plains in the evenings (Spinage 1994).

### Mate-Finding

Movement in elephants, where they are headed, and how fast they move to get there, can also depend on reproductive status, not just on resource availability (Mackey 2014). This is especially true in bulls, which range in search of cows regardless of resource availability (Spinage 1994). Bulls search for cows during the periodic condition of musth, during which they release an oily secretion from their temporal glands, which identifies them to cows (Nimura et al. 2014). Though African Savannah cows cover shorter distances during the drier seasons due to a shortage of foliage, bulls may travel longer distances to find mates (Birkett et al. 2012). Bulls not only find females by olfaction, but through acoustic signals (de Silva 2010). Intense mating can occur during large aggregations, though these incidents seem to be opportunistic as the reason for grouping is thought to be the availability of food (Spinage 1994).

### Conclusion

Elephants are often associated with grandiose ideas of navigation and migration; however, elephant movements are not always so simple. Elephants rely heavily on their senses to get where they are going, especially acoustics and olfaction.

Typically, African elephants are led by a matriarch, which relies heavily on memory to navigate, even following a cognitive map. Elephants move following the availability of food and water, which both depend on rainfall events. Specifically, bull elephant movements are influenced by the need to reproduce, while cow movement usually follows vegetation. Proboscidea navigation is a fascinating topic and one that will undoubtedly be studied for generations to come.

## Definition

An endogenous steroid hormone, derived from cholesterol.

## Summary

The effects of progesterone on the brain and behavior have been studied since the early 1900s. Across vertebrate taxa progesterone has been linked to the regulation of reproduction (Adkins-Regan 2005) (Fig. 1). Beyond reproduction, researchers in the fields of animal behavior, behavioral endocrinology, and neuroendocrinology have utilized a variety of techniques and methods to investigate the role of progesterone in a range of behaviors across contexts. Some of the long-standing methods used include the measurement of steroids via enzyme and radioimmunoassays, pharmacological manipulations (e.g., progesterone and progesterone receptor (PR) antagonists) both globally and locally in the brain, and autoradiography to describe the distribution of PRs. To further elucidate PR function, those techniques have recently been complemented by the integration of genomic methods and technologies such as targeted disruption of PR action via administration of antisense oligonucleotides and mutant strains of mice with PR deficiencies. Interdisciplinary research on progesterone has revealed interesting differences in the effects of progesterone across species and has led to many new discoveries in the molecular mechanisms by which steroids act in the brain to affect behavior.

## A Classical Endocrinology Perspective: Where Is Progesterone Made and How Does It Act?

Progesterone is a steroid hormone that is produced in the gonads and adrenal glands. Unlike some hormones, such as oxytocin and prolactin, steroid hormones are not encoded within the genome, but rather are derived from cholesterol via the activities of steroidogenic enzymes (Fig. 2). Progesterone occurs relatively early in the steroidogenic pathway (Fig. 2); thus in addition to effects via its own receptor, it can also function as a pro-hormone and be converted into other behaviorally relevant steroids (e.g., corticosteroids, androgens, and/or estrogens) in target tissues.

**Progesterone, Fig. 1** Endogenous cycles of progesterone across species. Panels (a–c) show circulating estradiol and progesterone in female mammals: (a) and (b) depict changes in female rats and mice across the estrus cycle (Redrawn from Walmer et al. 1992 mouse; Butcher et al. 1974 rat); (c) depicts changes in macaques across the menstrual cycle (Redrawn

from Kromrey et al. 2015). Panels (d–f) show circulating progesterone levels in female and/or male birds. (d) Ring doves, *Streptopelia capicola* (Redrawn from Silver 1978). (e) Starlings, Sturnidae (Redrawn from Ball and Wingfield 1987). (f) Wild zebra finches, *Taeniopygia guttata* (Redrawn from Prior et al. 2016).

**Progesterone, Fig. 2** A simplified schematic of the steroidogenic pathway. Panel (a) shows cholesterol conversion into progesterone by two steroidogenic enzymes (cholesterol side-chain cleavage enzyme and *3β-HSD* 3-beta hydroxysteroid dehydrogenase). Panel (b) shows the

downstream modifications that progesterone goes through as it is metabolized into glucocorticoids (depicted in green), androgens (depicted in red), and estrogens (depicted in blue)

Progesterone's effects on behavior are largely mediated by its action in the brain. As with other steroid hormones, progesterone is membrane permeable and thus can easily cross the cell membrane and bind the cytosolic PR. Ligand-bound PRs then form dimers that bind DNA and function as transcription factors, affecting physiology and behavior through modification of gene transcription (Fig. 3).

### Distribution of the PR in the Vertebrate Brain

The distribution of PRs has been described across several vertebrate taxa, including some species of lizards, frogs, and fish as well as several bird and mammal species. Most of the behavioral effects described here have been associated with PR action in key brain regions within the hypothalamus, the amygdala, and the striatum. Variation in the expression of PR within these brain regions has been related to

variation in social behavior. There are two primary progesterone receptors (PR-A and PR-B), which affect transcriptional activity of PR-responsive genes to differing extents. Generally these receptors co-occur in specific brain regions. However, the ratio of PR-A and PR-B in these regions is hormone-, region-, and sex-dependent (Becker et al. 2007).

### Beyond the Classical Perspective

There exist many nuances and complexities at each level of progesterone action described above in the classical perspective (Mani and Oyola 2012). Importantly, such complexities likely reflect the potential for subtle and context-dependent effects of progesterone on the brain and behavior:

- Steroidogenic enzymes have been found throughout the vertebrate brain, and evidence that the brain can synthesize steroids de novo

**Progesterone, Fig. 3** Schematic illustration of the two predominate modes of action of progesterone. One pathway, steps 1–3, shows progesterone binding to intracellular cytosolic progesterone receptor (PR), dimerizing and

affecting gene transcription. A second pathway, steps A and B, shows progesterone binding to a transmembrane protein receptor, having subsequent effects in the signal transduction pathway

from cholesterol has been confirmed in numerous species. This means the brain itself can synthesize progesterone during periods when circulating levels are low.

- Allopregnanolone, a predominately brain-derived metabolite of progesterone (Fig. 2), is a potent ligand for the GABA<sub>A</sub> receptor (the receptor for GABA, the primary inhibitory neurotransmitter). This discovery in the 1980s explained why large doses of progesterone had anesthetic and barbiturate effects.
- Progesterone can bind to transmembrane receptors (Fig. 3), which can activate rapid nonclassical signal transduction pathways (via activation of second messenger signaling or kinase cascades) and could impact behavior within minutes.

- The PR can have genomic effects in the absence of progesterone binding, through ligand-independent activation by coregulators or through binding of alternate steroids such as estradiol or neurotransmitters.

### Differential Effects of Progesterone on Sexual and Receptive Behavior in Rodents

Extensive research has been conducted on progesterone and female sexual behavior in rats, guinea pigs, and mice (Blaustein and Mani 2007). Some of the earliest research used ovariectomized rodents to identify the dose and timing of steroids necessary in order to activate reproductive and

sexual behaviors. The generalizable pattern that has emerged is that several “priming” doses of estradiol followed by progesterone exposure are required to elicit an optimal behavioral response. This relationship is largely due to the fact that estradiol is a potent regulator of the PR gene. Following estradiol priming, lordosis, the paracopulatory behavior associated with female receptivity in rodents, can be observed within 1 h of progesterone treatment and is maximal 2 h after treatment (Glaser et al. 1983).

The primary mechanism through which progesterone regulates female sexual behavior appears to be through genomic PR action. For example, female PR-deficient mutant mice are sexually unresponsive to progesterone administration following appropriate priming of estradiol. However, a general caveat with mutant mice strains is that the targeted gene disruptions are present throughout development; thus, it is not possible to distinguish between the effects of hormones on the organization of the brain during development versus acute effects of treatment in adulthood.

### **Role of Progesterone in Courtship Parental Behavior and Pair Bonding in Birds**

Identification of progesterone as a regulator of avian reproductive behavior dates to the 1940s. Research on poultry demonstrated that progesterone inhibits egg laying and identified the female oviduct as a key target of progesterone action. Some of the earliest behavioral research examined the role of progesterone in the regulation of courtship and parental behavior in male and female ring doves. Like the majority of bird species, ring doves form monogamous pair bonds and engage in biparental care. Komisaruk (1967) chronically implanted progesterone into different brain areas in both males and females in order to determine where progesterone was acting in the brain to influence behavior. Progesterone implants in the preoptic nuclei and lateral forebrain were found to induce parental behavior (incubation) in both males and females but inhibited male courtship behavior.

A more recent study by Smiley et al. (2012) investigated the role of progesterone on pairing behavior in another monogamous bird species, the Australian zebra finch. Here the authors focused on comparing the effects of progesterone administration on pairing behavior during courtship and bond formation versus pairing behavior after bond formation (pair bond maintenance). Interestingly, they found that while injections of progesterone increased pairing behavior (e.g., clumping) during pair bond formation, they saw no effect of progesterone administration on pairing behavior in couples that already had established pair bonds.

### **Progesterone in the Avian Sex Role Reversed**

Although progesterone has been widely implicated in the regulation of reproductive behaviors, there are many interesting species-specific differences in how this occurs. One great example of such variation can be seen in free-living female African black coucals, *Centropus grillii* (Goymann et al. 2008). In this species females are polyandrous (having several male mates) and defend territories. Whereas for many temperate breeding songbirds testosterone is implicated in the regulation of territorial aggression, in this species research suggests that progesterone is a key hormone regulating the timing of territorial aggression by attenuating female aggressive displays. Further research could clarify whether progesterone is affecting behavior via action on its own receptor or whether it is functioning as a prohormone.

### **Progesterone in Whiptail Lizards**

Another stunning example of the variation that exists is the role of progesterone in sexual behavior of whiptail lizards. *Cnemidophorus uniparens* is a unisexual (all-female) species of whiptail lizard. In this species, like closely related species of whiptail lizards, females become sexually receptive when preovulatory estradiol is high. However, *C. uniparens* females have increased

fecundity if they have copulated (sperm is not necessary). During the postovulatory phase, when progesterone levels are high, *C. uniparens* females will mount other females and thus facilitate reproduction of other individuals (Crews et al. 1986). Interestingly, although it is not as effective as testosterone, progesterone also stimulates mounting in castrated males of another closely related species, *C. inornatus*.

### Progesterone and Social Dominance in the African Cichlids

African cichlids are model species for research on the physiological basis of social behavior. In the species *Astatotilapia burtoni*, males can be dominant (brightly colored and aggressive defenders of territories) or subordinate (dull in coloration and reproductively suppressed). Interestingly, PRs have different effects on dominant and subordinate males. In dominant males, PRs facilitate courtship behavior, whereas in subordinate males it appears to modulate their perception of social threats (O'Connell and Hofmann 2012). This is a good illustration of the context-dependent effects of progesterone.

### Progesterone and Cognition in Animal Models

The majority of research focused on the effects of progesterone on cognition is motivated by a desire to understand the side effects of contraceptives and hormone replacement for women. There are several lines of research in rodents and nonhuman primates testing the effect of combinations of progesterone- and estradiol-like hormones paralleling the human pharmaceutical options on various aspects of cognition (Lacreuse 2006).

For example, Kromrey et al. (2015) related circulating progesterone levels in female cynomolgus monkeys to the acquisition and maintenance of a discrimination operant task. Consistent with the patterns described in humans, they found relationships between progesterone levels and performance during the acquisition

but not maintenance phase. Specifically, females with higher progesterone levels took more trials to acquire the discrimination task and made more errors.

In general, although the effects of progesterone appear to depend on the task, the general pattern that has been described is that progesterone is detrimental to female cognition. From human research, progesterone seems to predominately have negative effects on cognitive tasks involving spatial reasoning, target direct motor tasks, and mathematical reasoning, whereas progesterone seems to have no effect and may even improve performance on tasks involving verbal fluency and fine motor skills.

### Conclusion

This article provides an introduction to the basic endocrinology of progesterone, the methodologies researchers use to study the effects of progesterone on animal behavior and cognition, as well as a brief overview of some of the key findings from both classical and recent research. While progesterone has fundamental and essential functions as a female reproductive hormone, it also has context-specific effects on a wide range of behaviors and cognition in both males and females. Future research is likely to expand on our current knowledge by further describing the environmental factors influencing complex signaling pathways of progesterone and linking these neuroendocrine mechanisms to progesterone's context-dependent regulation of behavior.

## Definition

A polypeptide hormone associated with parental care, lactation, osmoregulation, reproduction, and immune function in vertebrates.

## Introduction

Prolactin (PRL) is a 23 kDa single-chain polypeptide hormone most notable for being associated with parental care in vertebrates and lactation in mammals and some bird species. While named for its role in lactation, prolactin is also important for osmoregulation in fish and acts both directly and via interaction with other hormones in functions throughout the body.

## Overview

Evolution of prolactin is hypothesized to be the result of gene duplication, which also produced growth hormone (GH) and somatolactin (SL) (Ocampo Daza et al. 2009). Prolactin was named by Oscar Riddle who purified it and developed its original bioassay. However, prolactin is an extremely versatile hormone that is associated with over 300 biological functions (Bole-Feysot et al. 1998; Freeman et al. 2000; Whittingham and Wilson 2013). Prolactin is a conserved hormone across the vertebrate clade. With reference to behavior and cognition, it is associated with reproduction and parental care in some species. However, it also plays roles in osmoregulation, growth and development, metabolism, angiogenesis, integument regulation, and immune function (Freeman et al. 2000; Marano and Ben-Jonathan 2014; Horseman and Gregerson 2014). Both circadian and circannual rhythms in prolactin secretion have been observed (Freeman et al. 2000).

Prolactin is mainly secreted from lactotroph cells in the anterior lobe of the pituitary. Studies of radiolabeled prolactin indicate that it can cross the blood-brain barrier (Freeman et al. 2000; Marano and Ben-Jonathan 2014). Extrapituitary prolactin has been found in various regions of the

brain, spinal cord, ovaries, decidua, tonsils, thymus, lymph nodes, spleen, lacrimal gland, sweat glands, hair follicles, skin, endothelial cells, mammary glands and their adipose deposits, cochlea, and male gonads (Bole-Feysot et al. 1998; Freeman et al. 2000; Marano and Ben-Jonathan 2014). Prolactin can act as a regulator of immune function and is associated with lymphocytes; extrapituitary prolactin expression has been observed throughout the immune system (Marano and Ben-Jonathan 2014). Prolactin receptors (PRLR) are members of the class I cytokine receptors and have been found in many tissues throughout the body including the mammary glands, brain, pituitary, uterus, ovaries, thymus, spleen, liver, pancreas, adrenal glands, heart, integument, gills, intestine, kidney, fertilized eggs (fish), bones, skeletal muscle, central nervous system, and in immune cells (including monocytes, macrophages, lymphocytes, natural killer cells, and granulocytes) (Freeman et al. 2000; Bole-Feysot et al. 1998; Whittingham and Wilson 2013).

The prolactin signaling mechanism is known as the JAK-STAT pathway. This involves phosphorylation of tyrosine kinase Jak2 and consequent phosphorylation of several STAT transcription factors (Freeman et al. 2000). Prolactin may influence the MAP kinase pathway (Whittington and Wilson 2013). It may occur in multiple isoforms within a species and is highly similar in structure to another hormone of the anterior pituitary, growth hormone (GH). The prolactin receptor also occurs in multiple isoforms with variable function (Freeman et al. 2000). Human GH is a functional ligand for human PRLR, though it binds differently from PRL suggesting flexibility on the part of the receptor in ligand activation (Langenheim et al. 2006). Additional prolactin-like proteins can also function as auto- or paracrine ligands for PRLR. Similarity to GH can complicate the study of prolactin in nonmodel organisms, particularly where animals are treated with exogenous hormone derived from a different species. Prolactin and prolactin receptor genes have been cloned in mammals, birds, reptiles, amphibians, and fish (Kato et al. 2005).

## Function in Vertebrates

### Fish, Amphibians, and Reptiles

In fish, prolactin has been implicated in osmoregulation, reproductive development and cycling, migration, pigmentation, immune function, growth, and parental care (e.g., mouth brooding, nest building/pit-digging, nest fanning, nest defense, nutrient provisioning) though specific function varies across species (Whittingham and Wilson 2013). It is likely important for development in anadromous fish where prolactin appears to mediate the osmoregulatory changes required for acclimating to changes in water salinity, with specific implication in adaptation to freshwater (Whittingham and Wilson 2013). Increased prolactin, both circulating and mRNA expression, has been associated with changes in water salinity, with implications that it may influence migratory behavior; however, its role here is not well understood (Whittingham and Wilson 2013). In amphibians, prolactin secretion has been observed in association with developmental metamorphosis; while several relevant actions have been documented, the details of its role remain controversial (Denver 2013). Prolactin purification has not been confirmed through development of a bioassay in reptiles, and study of its effects in this clade is limited (Norris and Carr 2013). Molecular study of prolactin gene expression has been conducted in at least one reptile species (Kato et al. 2005).

### Birds and Mammals

In birds, prolactin is associated with parental care (i.e., contact incubation, broodiness, chick-feeding, and alloparenting) in both sexes and lactation in several species that produce crop-milk (Buntin 1996). Prolactin increases with the duration of incubation period in birds and, while generally attributed to incubation behavior, must act in concert with sex steroid hormones to induce and maintain contact incubation in adults (Buntin 1996; Angelier et al. 2016). In Columbiformes (i.e., pigeons and doves) circulating prolactin levels are delayed, not rising until 5–7 days into incubation, which has been attributed to the production of crop-milk that parents of this group

feed their young (Buntin 1996). The induction of crop-milk in pigeons was significant as an early quantitative bioassay used to measure hormone levels in mammalian samples (Horseman and Gregerson 2014). Prolactin also mediates parental response to chick food demand with parents responding to increased begging of food-deprived chicks with higher feeding rates, increased prolactin secretion, and higher crop-milk production (Buntin 1996); however, species differences in circulating prolactin vary during the chick-rearing period (Buntin 1996). This variation during the chick-rearing period is associated with altriciality, meaning precocial birds tend to decrease prolactin, while altricial birds maintain higher levels (Buntin 1996; Angelier et al. 2016). Prolactin has also been implicated in premigratory fattening in some avian species (Wingfield et al. 1990).

In mammals, it is associated with reproductive development and cycling, lactation, and maternal behavior though the influence of prolactin differs between groups (e.g., prolactin is associated with maternal behavior in rodents but does not seem to be important in nonhuman primates, Freeman et al. 2000). It is also generally associated with paternal behavior in mammals though, again, this is not universal (Nelson and Kriegsfeld 2016). During lactation, circulating prolactin acts in concert with other hormones to stimulate the mammary glands to produce milk (Freeman et al. 2000). Some prolactin makes its way into milk where it is ingested by the young and plays a role in the maturation of several key systems (i.e., immune and neuroendocrine, Freeman et al. 2000).

### Common Promoters and Inhibitors

Prolactin is stimulated by nursing young in mammals and inhibited by stressors. The presence of young stimulates secretion of prolactin (Buntin 1996). In both birds and mammals, stress (and associated glucocorticoid hormones) is associated with reduced circulating prolactin levels (Freeman et al. 2000; Angelier et al. 2009; Angelier et al. 2016). This inhibition is primarily controlled by the hypothalamus through prolactin-releasing factors and prolactin-

inhibiting factors. In birds, increased circulating corticosterone and lower prolactin levels are correlated with lower levels of parental investment (Angelier et al. 2009; Angelier et al. 2016).

Hormones that generally promote increases in prolactin in mammals include vasoactive intestinal peptide (VIP), thyroid-releasing hormone (TRH), oxytocin, vasopressin, cytokines, galanin, neurotensin, serotonin, gonadotropin-releasing hormone, estradiol, ghrelin, and growth hormone secretagogue (Freeman et al. 2000). Common inhibitors of prolactin include dopamine, GABA, somatostatin, prolactin, acetylcholine, glucocorticoids, and cannabinoids (Freeman et al. 2000). Opioids, by blocking dopamine, may increase PRL. A hypothalamic inhibitory regulator, presumptively referred to as “prolactin release inhibitory hormone” (PRIH), is most likely dopamine (Freeman et al. 2000, Norris and Carr 2013). Other hormones (e.g., estrogen, progesterone) may also influence tissue responsiveness to prolactin, resulting in synergistic or antagonistic effects (Norris and Carr 2013).

## Promiscuity

Francisco Garcia-Gonzalez

Doñana Biological Station, Spanish Research Council (CSIC), Sevilla, Spain

Centre for Evolutionary Biology, School of Biological Sciences, The University of Western Australia, Crawley, WA, Australia

## Definition

Indiscriminate mating with multiple partners

## What Is Promiscuity?

Promiscuity means mating with multiple partners in an indiscriminate way, that is, without any selection-based process or quality-based discrimination of mating partners. Contrary to popular belief, promiscuity does not merely mean mating or engaging in sexual activities profusely with different partners. The misuse of the term “promiscuity” in behavioral sciences and evolutionary biology has been pointed out before (Elgar et al. 2013), and the improper use of the term extends to other areas including evolutionary psychology.

The “without choice” qualifier of the term is important because in spite of the fact that males and females mate with multiple partners in most sexually reproducing animal species, in the majority of these species sexual interactions are governed by mate selection criteria. Thus, applying the strict and correct definition of promiscuity would render very few animals promiscuous indeed. Conversely, if a broader definition of promiscuity was used (e.g., as in “to mate with multiple partners”), then most sexually reproducing species would exhibit promiscuity.

## Promiscuity and Mating Systems

Mating systems are defined by whether individuals associate with one or more sexual partners, and by the sex that engages in multiple sexual interactions with members of the opposite sex. Polyandry occurs when females mate with several males within the same reproductive cycle, polygyny defines the system where males mate with multiple females, and polygynandry takes places when both sexes engage in sexual interactions with multiple partners. These three mating systems are polygamous systems, meaning that either sex or both of them mate with multiple individuals of the opposite sex. They differ from a monogamous mating system in that in such a system each individual of a given sex mates just with one individual of the opposite sex (at least during each discrete reproductive cycle). Promiscuous behavior is possible within polygamous mating systems. It may also occur under social

monogamy if individuals engage in copulations outside the social pair-bond (extra-pair copulations).

The terms to define the different mating systems are also used to define behaviors. For instance, polyandry is generally used in the scientific literature to denote the multiple-mates mating behavior of females, even if this behavior occurs outside a formal polyandrous mating system in which females monopolize males. Henceforth, polyandry and polygyny terms will be used in this broad sense, that is, referring to the behavior of multiple mating of females and males respectively.

Interestingly, it has become apparent that many so-called monogamous species are monogamous from a social, but not from a genetic, perspective. The application of modern DNA fingerprinting technology has revealed overwhelming evidence that female multiple mating, the ensuing sperm competition (competition among the sperm from two or more males for the fertilization of a female's ova), and multiple paternity are much more widespread phenomena than it was previously thought (Birkhead and Møller 1998; Birkhead 2000; Barash and Lipton 2001). As an example, the male-female pair bonds established by the great majority (90%) of bird species have proven to be not so tightly bonded. Paternity analyses of broods have uncovered that females in over 70% of these “monogamous” species engage in extrapair copulations (Birkhead 2000; Griffith et al. 2002). In other words, most bird species are socially monogamous but they exhibit genetic polyandry (and genetic polygyny). And this is just a small representation of the extent of multiple mating in nature.

## Is Multiple Mating Widespread? Is Promiscuity Widespread?

When it comes to sex, males are often seen as willing, indiscriminate, eager, rampant, sexually demanding, or predisposed for multiple sexual partners. Indeed, in most sexually reproducing species, there is selection on males to mate multiply for well-known reasons rooted in biology, as

discussed below. As for females, they have traditionally been seen as reluctant to engage in sexual interactions with multiple partners, and they have been often defined as acquiescent, coy, or sexually reticent. There is, nonetheless, increasing evidence that this is a simplistic assumption.

Female multiple mating can be found in innumerable species of fish, a great deal of mammal species, many primates including chimps and bonobos, crickets, beetles, numerous fly species, butterflies, damselflies, and many other insect species including members of social insects groups (e.g., some bees, such as honeybees, and several species of ants and wasps), dolphins, most (over 90%) species of birds including socially monogamous species, horseshoes crabs, snails, arachnids, many reptiles, a great deal of amphibians, octopuses and other cephalopods, crustaceans, sharks, and the list continues on and on. By contrast, monogamy (or monandry) is much less frequent. Monogamy occurs in some species of blowflies, several species of social insects including termites, some fish including the majority of seahorses, a handful of species of birds (e.g., geese, some woodpeckers and passerines, swans, kittiwakes, some raptors including owls, etc.), beavers, and a few other species in other groups. Monogamy is the rule in less than 10% of all mammal species, and this includes genetic monogamy and species that form pair-bonds (which are not necessarily sexually monogamous, although unlike birds social monogamy in mammals is generally associated with genetic monogamy) (Lukas and Clutton-Brock 2013). Social monogamy occurs in around 30% of all primate species (e.g., hamadryas baboons), and monogamy has also been documented in some species of bats (6%) and rodents (6%), around 15% of carnivores (notably foxes and coyotes), and less than 3% of ungulates. True monogamy of course occurs less frequently than the percentages shown previously because social monogamy does not always translate into genetic monogamy. Overall, monogamy is not so common or ubiquitous as multiple mating across the animal kingdom.

As for humans, anthropological studies have indicated that strict social monogamy is rare (less

than 20% of human cultures). It has been estimated that around 80% of human societies were preferentially polygynous before their contact with Western cultures. Polyandry as a formal or accepted mating system is exceedingly uncommon, but nonetheless female multiple mating still has some incidence in monogamous or polygynous societies due to extrapair copulations (Simmons et al. 2004; Barash and Lipton 2001; Barash 2016). Female multiple mating is quite common in some cultures (e.g., 70% of Amazonian cultures (Walker et al. 2010)), but genetic analyses indicate that rates of extrapair paternity due to female multiple mating in contemporary Western societies, and through historical times, is low (between 1% and 2%) (Larmuseau et al. 2016). It is important to note, however, that rates of extrapair paternity are a lower limit for rates of female multiple mating since not all matings result in fertilizations (e.g., due to the coitus taking place outside the female's peak fertile period, or to other traditional or modern contraceptive methods).

In summary, most animals exhibit polygamous mating systems or socially monogamous mating systems with varying rates of extra-pair copulations. This does not imply that promiscuity is a ubiquitous behavior. Despite the taxonomic spread of polygamous behavior, research into sexual selection over the last decades has proved that mating preferences are prevalent in all mating systems (Jennions and Petrie 1997). In most primates, as in most other groups, mating preferences for particular males or females are well known. Bonobos are reportedly claimed to behave "promiscuously" to resolve conflicts, and some human groups or individuals are labeled by some people as "promiscuous," but in the majority of cases (perhaps not all) this is the result of a frivolous use of the term.

Mate choice implies that promiscuity *sensu stricto* is infrequent. Some of the best candidates for truly promiscuous animals could be encountered among external fertilizers and in particular broadcast spawners. In these species, multiple individuals of both sexes release their sex cells into the water and so any individual may mate quite indiscriminately with a large number of individuals from the opposite sex. However,

recent discoveries are starting to reveal that even in broadcast spawners such as in some species of sea urchins and mussels, reproduction includes a component of choice at the level of gamete interactions (Evans and Sherman 2013; Evans et al. 2012; Levitan and Ferrell 2006). As for other external fertilizers such as fishes and amphibians mate choice is well documented.

### **Differences Between the Sexes, Sex Roles, Sexual Stereotypes, and Promiscuity**

Typically males and females have different strategies to maximize fitness through sexual reproduction. Many of the disparities between the two sexes in regard to reproduction can be rooted to baseline differences in gamete size between males and females (Trivers 1972). In fact, the size dissimilarity in the sex cells is essentially what defines the sexes: within any given sexually reproducing species the kind of individuals that manufactures relatively smaller (but abundant) gametes are called males, whereas individuals from the sex producing relatively larger (and fewer) gametes are called females. This asymmetry in gamete size (anisogamy) has far-reaching implications for sex roles. For a start, the disparity in gamete size implies that from conception there are differences between the sexes when it comes to the investment they make in the offspring. The female ovum provides the nutrients for the embryo, and females generally provide the environment for embryo development. Males, on the other hand, typically contribute little more than the DNA contained in a minuscule cell. This initial asymmetry in parental investment generally deepens as the offspring develops, especially in vertebrates, with females making a much greater effort protecting or nurturing the embryos and even the young after birth. For instance, pregnancy in a typical mammal lasts several months (e.g., 12 months for horses, 22 months in the case of elephants), and this is followed by lactation. Thus, maternal investment is substantial compared to paternal investment. In other groups, the difference in

parental investment between the sexes is not so large but it is still apparent.

The asymmetry in gamete size also means that the sex producing smaller sex cells produces many more gametes (and at a lower energetic and physiological cost per gamete) than the opposite sex: males typically produce astronomical numbers of gametes, and at a much higher production rates than females. An outcome of this is that males generally compete for access to the limiting resource that allows them to maximize their biological fitness: females, or from a reductionist's point of view, their ova.

Anisogamy and all its direct and indirect implications mean that males can theoretically father hundreds or thousands of offspring with different partners (at the expense of other males). This is well known, and in fact, put into practice, by animal breeders. In contrast, females typically have lower potential reproductive rates (measured in terms of number of offspring) due to them producing fewer gametes (sometimes a fixed low number of ova in a lifetime) and investing a great deal of time and effort into the offspring. In short, sexual differences in gamete size has created reproductive competition among males and asymmetries between the sexes over parental investment and reproduction, with the consequence that male reproductive success is usually limited by the number of mates while female reproductive success is limited by gamete production (Trivers 1972; Bateman 1948; Kokko et al. 2006; Kokko and Jennions 2008; Janicke et al. 2016).

As a consequence of these biological underpinnings, males are expected to be comparatively indiscriminate and females comparatively choosy, and males are expected to be keener than females to engage in multiple matings. Females are expected to maximize their reproductive success with only one or a few matings, and would benefit to a larger extent from careful mate discrimination to ensure their energetically and time-expensive parental efforts go into highly viable or attractive offspring. In humans, for instance, cross-cultural sex differences in sex drive and sociosexuality are well documented, with men typically having more sociosexually unrestricted attitudes and behaviors

than women (Schmitt 2005; Lippa 2009). Anisogamy and parental investment disparities are therefore at the core of many morphological, physiological, and behavioral differences between the sexes in regard to sexual interactions. In the context of the evolutionary drivers of promiscuity, males would thus be expected to benefit more from promiscuous behavior than females, but evidence shows that mate choice underlies, in general, male mating decisions too (Edward and Chapman 2011; Shackelford et al. 2005).

### **Why Do Animals Mate Multiply? And Why Do They Engage in Promiscuous Matings?**

As discussed in the previous section, it is easy to envisage the benefits of multiple mating for males. Sperm is generally produced on a continuous basis, the cost of producing a single sperm, compared to an ovum, is much lower, and male parental investment is low. Thus, males can ultimately maximize fitness (in terms of number of offspring sired) in a more or less proportional way as they increase the number of mating partners. Indeed, polygyny is very common in the animal kingdom. As for females, as a result of anisogamy and a high parental investment they are expected to maximize reproductive success with only one or a few matings. Moreover, the sperm from a single copulation are usually enough to ensure fertilization of the complete set of a female's ova. Finally, mating generally entails costs (for instance, increases in the risk of contracting sexually transmitted diseases), and mating outside the pair bond may entail important costs such as mate desertion in species with biparental care. Consequently, female multiple mating would not be expected to be a common and widespread behavior. Nonetheless, as indicated above polyandry is virtually ubiquitous among sexually reproducing species. Explaining this discrepancy between observation and theory has received considerable attention in recent times (though it is also possible that monandry rather than polyandry is what requires an adaptive explanation; see Kokko and Mappes 2013).

Female mating frequency may be explained, at least in some species, by selection on males to

maximize their reproductive success, that is, by sexual conflict leading to higher-than-optimal mating rates for females (Arnqvist and Rowe 2005). In some other cases, it may be less costly for females to accept copulations than to suffer male sexual harassment (convenience polyandry). In other situations, notably in mammals, female multiple mating may have evolved to create paternity uncertainty so as to deter infanticide. Notwithstanding, from a broader point of view, the evolutionary maintenance of polyandrous behavior is more easily understood when polyandry entails benefits. Indeed, females in some species obtain direct (also known as "material") benefits from males at copulation. For instance, females can obtain nutrients in the form of food items or substances transferred in the ejaculate during copulation, or by mating multiple females can generate slight confusion regarding paternity and in this way increase the number of partners willing to share care duties, or they may gain access to better territories, or females may mate multiply to ensure fertilization of the ova (fertility insurance).

Regardless of the presence of material benefits, polyandrous females can also obtain genetic benefits from mating multiply. These are benefits that are manifested in the offspring. For instance, females may "trade-up" to obtain good genes for their offspring when a male is considered of superior genetic quality than the female's previous mate. The traditional "good genes" and "sexy sons" hypotheses hold that females that mate with additional males may increase their fitness indirectly through their offspring because of the inheritance of "good genes" or "attractive genes" (Garcia-Gonzalez and Simmons 2005; Neff and Pitcher 2005).

In addition, one of the most frequently invoked genetic benefits from polyandry in recent years is based on processes that allow females to avoid the negative effects that arise from mating with genetically incompatible males (Neff and Pitcher 2005; Evans et al. 2007). Alternatively, females may engage in copulations with several males to increase the diversity of paternal genotypes in their offspring so that the likelihood that at least some offspring will survive in a changing environment is higher than when offspring genotypes are less diverse (that is, when the females mate monogamously). Finally, females may behave

polyandrously if by mating with multiple males they reduce the risk of having all their offspring sired by a male of low genetic quality (henceforth reducing the risk of potentially losing entire clutches because of low offspring viability). Such risk spreading strategies of the kind “don’t put all your eggs in one basket” are known as bet-hedging polyandry (Garcia-Gonzalez et al. 2015; Yasui and Garcia-Gonzalez 2016).

### **Promiscuity, Direct Benefits, and Bet-Hedging**

Studies have found evidence that females frequently obtain one or several of the benefits above mentioned when they mate with multiple males. However, as it has been pointed out repeatedly in this article, some form or another of female (and male) mate choice is the norm across human and nonhumans, in which case there is no room for talking about promiscuous (indiscriminate) sexual behavior. Nevertheless, promiscuity is compatible with the accrument of direct, and in some circumstances, indirect benefits of mating. Promiscuous behavior is more likely to occur when mating entails direct or material benefits because individuals would obtain the resource (access to food, for instance, in nuptial feeding species) as long as they mate, even though there might be variation in the quality of resources held by potential mates. Indirect benefits are unlikely to explain the evolution of promiscuous behavior in general, because the magnitude of indirect benefits accrued increases following mate quality discrimination and mate choice. For example, high-quality individuals are expected to express traits that indicate their higher reproductive value, and individuals of the opposite sex would be selected to discriminate these signals insofar mating with high-quality individuals gives rise, due to inheritance, to high-quality offspring. Most hypotheses to explain the maintenance of polyandry are based on the existence of mate choice, and the vast majority of indirect (genetic)-based pay-offs from multiple mating are not expected to be responsible for the evolutionary maintenance of promiscuity, because if individuals can discriminate mate quality they will do so.

There are nonetheless, a few exceptions. For example, if males that attain higher fertilization success via sperm competition sire offspring with higher viability or higher attractiveness, females that mate multiply will increase their fitness simply by facilitating sperm competition among their mates because they will produce attractive, competitive, or viable offspring sired by the most successful mate. This benefit can be obtained in the absence of mate choice, though some sort of female choice either before mating or after mating (e.g., via female-driven paternity biases known collectively as cryptic female choice) is normally in place.

Bet-hedging multiple mating is another hypothesis compatible with promiscuous behavior because a bet-hedging mechanism is based precisely on a lack of sire selection criteria. In some species, or under some circumstances, mate choice is unreliable, imperfect, or absent. In such cases, it may pay to mate multiply and indiscriminately rather than monogamously because, by doing so, individuals may reduce the risk of mating with an unsuitable (low quality, infertile, etc.) partner, or they may reduce the risk of having offspring sired by a single genetic background in a changing and unpredictable environment. In other words, by mating indiscriminately individuals may reduce the consequences of assessment errors when choosing a mate, or they may increase the genetic diversity of their offspring (Garcia-Gonzalez et al. 2015; Yasui and Garcia-Gonzalez 2016). The hypothesis of bet-hedging multiple mating is compatible with promiscuity because it just requires multiple mating, regardless of the phenotypic traits of the potential mates. Empirical tests of this hypothesis are, however, scant.

### **Conclusions**

It is important not to confuse promiscuity with polyandry, polygyny, or polygynandry (i.e., any form of polygamy). All these terms mean sexual encounters with multiple partners, but promiscuity is a restrictive term that in reality implies indiscriminate sexual behavior. There cannot be promiscuity without polygamy but there can be

polygamy without promiscuity, and in fact this is the most common case in nature. The advent of molecular tools applied to paternity analyses has revealed that multiple paternity within a single brood is commonplace. Multiple mating, either from the perspective of males (polygyny) or females (polyandry), is extremely common in the animal kingdom. In fact, true (genetic) monogamous mating systems have turned out to be exceedingly rare in nature. But, even though we currently know that mating with multiple partners is a common and ubiquitous behavior across animals and occurs with some frequency even in socially monogamous species, promiscuity is extremely rare because when it comes to sexual interactions some form or another of mate choice is the norm. Mate choice is also prevalent in the majority of the diverse range of traditional or modern nonmonogamous relationships or practices exhibited by humans.

## Introduction

Prosimians are a diverse group of primate species including the infraorders Tarsiiformes, Lorisiformes, and Lemuriformes. Primate cognition has interested researchers from varying disciplines ranging from psychology to anthropology. Primates are regularly expected to solve problems and scenarios that require a level of cognitive competence can be classified into two categories, physical and social cognition. Primates are unique among mammals in that they have a larger brain to body size ratio (Isler and van Schaik 2009). The corresponding cognitive capacity varies disproportionately across the order Primates (Dunbar 1992). Lemuriformes are by far the most studied infraorder relative to the other prosimians, but pale in comparison to the number of studies focused on New World primates, Old World primates, and Apes. In order to better understand cognitive abilities in primates, research on cognition in basal extant primates can contribute to our greater understanding of cognition in all primates including humans.

## Tarsiiformes

Few studies have examined tarsier cognition in the same ways that lemurs, lorises, and galagos have been tested both in captivity and in the wild. There have been some field experiments focused on predator response, where Gursky (2003) tested the response calls of mother and infant spectral

tarsiers in Sulawesi. She found that infants used specific alarm calls for terrestrial predators and another for aerial predators. These findings suggest that tarsiers use complex communication and some form of social learning to pass this information from mother to offspring.

## Lemuriformes

To survive in the wild, physical cognition aids in the ability to efficiently search for key resources (i.e., food and shelter). Orientation and efficient travel while using spatial cognition is seen in mouse lemurs, ring-tailed lemurs, mongoose lemurs, ruffed lemurs, and Coquerel's sifakas. Rosati et al. (2014) showed that frugivory elicited a stronger use of spatial memory, compared to folivory. Several diurnal lemur species were able to successfully complete object permanence tasks, including visible but not invisible displacements scenarios. Ring-tailed lemurs can implicitly learn spatial sequences picking up information from the environment without explicit instruction or conscious awareness of the learning process (Drucker et al. 2016).

Lemurs are able to understand numerical ascension; this is specifically seen in ring-tailed lemurs, who can apply these principles to numerosities, and in brown, mongoose, and ruffed lemurs, who can comprehend simple arithmetic. Furthermore, their sensitivity to numerical discrimination and accuracy in sequential memory are comparable to rhesus monkeys, and their order sequences tests are comparable to other haplorhines (Jones et al. 2014). Inhibitory control test are commonly used to measure behavioral self-control. MacLean et al. (2014) found that ring-tailed lemurs did not outperform other lemur species in inhibitory control studies whereas other researchers had different results when testing ring-tailed lemurs alongside, ruffed lemurs, mongoose lemurs, black lemurs, and Coquerel's sifakas. Though there are no reports from the wild or captivity, of unsolicited lemur tool use, it is also reported that they may have an understanding of tool functionality. Ring-tailed

lemurs were able perform equally to capuchins, tamarins, and vervet monkeys, when choosing between two tools, where one was functional for retrieving a reward and the other was not. A common cognitive trait seen in black, brown, red-fronted and ring-tailed lemurs are the ability to be trained in new skills and behaviors to complete puzzle boxes.

Ring-tailed lemurs live in large multi-male, multi-female groups and maintain dominance hierarchies, which are not acquired through matrilineal kinship (Kappeler 2012). Black, brown, mongoose, and ring-tailed lemurs use transitive interference at varying levels, which is a form of deductive reasoning (Tromp et al. 2015). Ring-tailed lemurs performed better than mongoose lemurs, suggesting that their varying group size influences the cognitive capacity for this mechanism (Kittler et al. 2015). Reconciliation after conflict, which is regularly seen and measured in higher primate taxa, has also been seen in ring-tailed, black, brown, and red-fronted lemurs, as well as Verreaux's sifakas. Coalitions are only formed in specific situations and tend to be female based and is only observed in ring-tailed lemurs, though red-fronted lemurs reportedly form partnerships while migrating (Gould 1997). Gaze follow, which is used to measure conspecific attention, is reported in ring-tailed, black and brown lemurs, as well as the ability to coordinate attention (Ruiz et al. 2009). Brown and ring-tailed lemurs are also able to follow human gaze (Botting et al. 2011; Sandel et al. 2011).

Various lemur species use social learning while transmitting information from one individual to another. O'Mara and Hickey (2012) found that infant and juvenile ring-tailed lemurs used generalized stimulus enhancement with older conspecifics to gain ecological knowledge; Hosey et al. (1997) also reported evidence of stimuli enhancement in ring-tailed lemurs. According to Fichtel and van Schaik (2006), the Verreaux's and Coquerel's sifakas and possibly the red-fronted display behavioral traditions. Regarding social intelligence, ring-tailed lemurs appear to be more skilled than other lemurs in using social cues during food competition tasks. They use specific

alarm calls for specific threats both aerial and terrestrial (Pereira and Macedonia 1991), whereas sifakas and red-fronted lemurs used specific alarm calls for aerial threats only (Fichtel and van Schaik 2006). These findings suggest that ring-tailed lemurs have a more complex communicative repertoire compared to other lemurs.

## Lorisiformes

Physical cognition in Lorisiformes is limited to a few studies in bushbabies and lorises; pottos and angwantibos are rarely considered in these tests. In object permanence and displacement testing, Jolly (1964) reported that one slender loris did not search for hidden food once it left its direct line of sight, but simply struck at the object covering the food item, which was later perceived as an inconclusive result accounting for the varying adaptation lorises may have for quickly grasping an item. Simply because they were unable to displace the obstructing object does not mean they do not have some concept of the food item once out of sight. Since Jolly's early work and following increased interest in basal primate cognition, researchers have provided evidence for a right-hand preference in wild-born *Nycticebus* spp. and a complex understanding of their physical environment.

During object manipulation tasks, Jolly (1964) found that the lesser bushbaby only struck at the objects, while the greater and thick-tailed bushbabies and the potto were more exploratory as they poked and pushed the food-baited novel objects. A similar study looked at novel object interaction in the greater bushbaby and found that they were interested in novel non-food baited objects, but preferred larger, more maneuverable objects. In numerical discriminate tasks, thick-tailed greater galagos were slower and less accurate in discrimination learning tasks but performed similarly to other primates in set-learning tasks. Researchers studying Garnett's greater bushbaby reported that they took longer to search for items that resulted in smaller rewards, suggesting that they could distinguish

between less and more. Garnett's bushbabies were also tested in regards to the approach-avoidance paradigm, where Hanbury et al. (2013) reported that they displayed a left hemisphere specialization during approach-related behaviors.

## Conclusion

Despite the perceived variation in cognitive ability across primate taxa, when it comes to basic cognitive abilities prosimians are not qualitatively different than other primates. Regardless of their smaller relative brain size, they display comparable and complex cognitive function, with regards to physical and social cognition. Though extensive research has been conducted on various lemur species, there is still much to learn among prosimians.

## Prosimian Communication

Sharon E. Kessler

Durham University, Durham, UK

## Synonyms

Galago; Lemur; Loris; Olfaction; Scent mark; Strepsirrhine; Tarsier; Vocalization

## Introduction

Prosimians are a group of primates which include lemurs, galagos, lorises, and tarsiers. They are diverse in their social systems, activity periods, and habitats. They may live in groups or forage solitarily, be diurnal or nocturnal, and live in diverse environments. They have complex, multimodal communication systems which rely heavily on auditory (vocalizations), olfactory (scent marks), and visual signals (movements and fur markings). These signaling modalities enable prosimians to communicate at various distances during both day and night and through different types of habitat. Both vocalizations and scent can be used to communicate between individuals that are near or far. Soft vocalizations are used for close range, and loud calls are used for distant individuals. Similarly, scent can be perceived by nearby individuals, or scent marks can be deposited to be detected by others long after the individual that produced it has moved away. Movement and fur color patterns are used to communicate at distances that are close enough for visual contact. These various communication modalities combine to enable prosimians discern information about an individual, potentially including species, individual identity, sex, reproductive status, and kinship relationships. Prosimians communicate while engaging in complex social interactions including maintaining ranges, attracting and searching for mates, and raising young.

## Vocalizations

The auditory channel is an important part of prosimian communication and the primary method of signaling is through vocalizations. Prosimian vocalizations vary greatly across species in acoustic range and usage. Most species vocalize in the range that is audible to humans (up to ~20,000 Hz), but a few species also have vocalizations which are either partially (mouse lemurs) or entirely (tarsiers) in the ultrasonic range (Ramsier et al. 2012; Zimmermann 1995). Because such ranges are above the hearing range of predatory birds, this is thought to be an adaptation for avoiding eavesdropping by predators (Ramsier et al. 2012; Zimmermann 1995).

Vocalizations have been shown to convey a great deal of information about the caller including species, sex, individual identity, and even kin group (citations below). Source-filter theory (Fant 1960) explains how such information is detectable in vocalizations. The source of the sound is air passing through the animal's vocal folds. The rate at which the vocal folds vibrate determines how high or low the sound is. Then as the sound waves pass through the vocal tract and out the mouth, different frequencies are amplified or dampened due to the morphology of the vocal tract. Because an individual's vocal tract morphology may vary according to its species, sex, individual identity, and kin group, this can produce voices that are distinctive by species, sex, individual identity, and kin group.

Of the prosimians, the lemurs are probably the most intensively studied. This research has shown that various lemur species have calls that are distinctive by species (sportive lemurs: (Méndez-Cárdenas et al. 2008), true lemurs: (Gamba et al. 2012b)), sex (sifakas: (Patel and Owren 2012)), individual identity (sifakas: (Patel and Owren 2012), red-bellied lemurs: (Gamba et al. 2012a), mouse lemurs: (Leliveld et al. 2011)), and kin group (mouse lemurs: (Kessler et al. 2014; Kessler et al. 2012)). Similarly, galago calls have been argued to be distinctive by individual (Kessler et al. 2015) and species (Anderson et al. 2000). In comparison, much less research has been done on the vocalizations of the lorises and

tarsiers, though vocalizations are increasingly used in species identification among the tarsiers (Burton and Nietsch 2010).

Research into the acoustic variations between individuals, populations, and species is currently under intense interest for its potential applications to conservation as a tool for identifying species and developing acoustic monitoring programs (Burton and Nietsch 2010). Such programs would enable conservationists to obtain a great deal of information about how these species – many of which are small, cryptic, nocturnal, and difficult to follow – use the forest without trapping them or disturbing them.

However, from the perspective of animal communication, it is important to distinguish between when the variability exists to statistically distinguish between species, individuals, sexes, or kin groups and whether the animals actually detect and use this information. This requires the use of playback experiments. During playback experiments, recordings of vocalizations are played, and the subjects' behavioral responses, like whether they look toward the loudspeaker, are measured. Playback studies have been used to show that prosimians may detect when vocalizations vary by species (mouse lemurs: (Braune et al. 2008)), individual identity (Kulahci et al. 2014), and kin group (mouse lemurs: (Kessler et al. 2012), ring-tailed lemurs: (Nunn 2000)).

Prosimians use vocalizations to communicate in many different social contexts. This includes both species that live in cohesive social groups and solitary foraging species. Vocalizations can be given as coordinated vocal displays, like the duets of sportive lemurs (Méndez-Cárdenas and Zimmermann 2009) and tarsiers (Burton and Nietsch 2010) or the loud group choruses given by Indri groups when engaging in territorial displays (Torti et al. 2012). Alternatively, vocalizations may be given without being part of a coordinated display but may still have important roles in social bonding (ring-tailed lemurs (Kulahci et al. 2015)), defense against predators (mouse lemurs (Eberle and Kappeler 2008), sifaka and red-fronted lemurs (Fichtel 2004), tarsiers (Gursky 2006)), maintaining spacing between individuals and group coordination (mouse lemurs (Braune et al.

2005), red-fronted lemurs (Pflueger and Fichtel 2012)), mate advertisement and territory defense (sportive lemurs (Seiler et al. 2015)), and rearing young (bush babies (Becker et al. 2003), mouse lemurs (Scheumann et al. 2007)).

## Scent Marking

Prosimians rely more on olfactory communication than do other primates. They are believed to have functional vomeronasal organs that help them to detect olfactory cues (Smith et al. 2015). Prosimians use several types of scent marks including latrines, fecal marking, urine marking, and/or urine washing (when the animal urinates on its own hands and feet, and then deposits the urine from the hands and feet as it travels), as well as marking using scent from the chin, forehead, palms, genitals, or specialized scent glands (Delbarco-Trillo et al. 2011). Sources of the scent may include feces, urine, saliva, sweat, skin, or secretions from glands in the genital, perianal, gular, sternal, brachial, or antebrachial regions (Delbarco-Trillo et al. 2011; delBarco-Trillo et al. 2012). Some species also mix scents from more than one source before depositing it (Greene et al. 2016).

Because much less is known about olfactory communication than vocal communication, studies comparing olfactory communication across prosimian species are still relatively rare. However, there have been a few studies which have begun to illuminate how olfactory communication has evolved in prosimians. Urine marking has been reconstructed as one of the oldest forms and is the main form of scent marking used by nocturnal, solitary foraging species such as the galagos, lorises, and several nocturnal lemurs (Delbarco-Trillo et al. 2011). Such urine marking may also take the form of urine washing. In general, these predominantly urine-marking species have more chemically complex urine, meaning that the urine contains more different compounds, than species which do not mark with urine (Delbarco-Trillo et al. 2011). The evolutionary shift from urine marking in nocturnal, solitary foragers to depositing scent from scent glands in

cathemeral and diurnal species is believed to have evolved due to the increasing social complexity in these species (Delbarco-Trillo et al. 2011). These species forage in cohesive social groups; thus, these marks may be important for both intragroup and intergroup communication (Delbarco-Trillo et al. 2011). Glandular scent marks can be highly complex relative to urine (Delbarco-Trillo et al. 2011). For example, the number of compounds found in urine ranged from 2 to 33, while ring-tailed lemurs may express 200 to 300 different compounds in their glandular secretions (Delbarco-Trillo et al. 2011).

This relationship between social complexity and chemical complexity in scent marks was also supported in a study comparing scent-mark chemistry and degree of sociality between eight *Eulemur* species (delBarco-Trillo et al. 2012). These species live in cohesive social groups with differing social organizations (pair-bonded or multi-male multi-female) and differing dominance relations between the sexes (female dominant or codominant). Interestingly, differences associated with social system and dominance relationships between the sexes were found (delBarco-Trillo et al. 2012). Female scent marks were chemically more complex in species that live in multi-male, multi-female groups relative to the marks of females of pair-bonded species (delBarco-Trillo et al. 2012). Similarly, male scent marks were more complex in species where males are codominant with females relative to the marks of males in female-dominant species (delBarco-Trillo et al. 2012). When the sexes were compared, males in codominant species had more complex scent marks relative to females in the same species (delBarco-Trillo et al. 2012). However, in female-dominant species, the females had more complex signals relative to the males (delBarco-Trillo et al. 2012).

Much less is known about the signal content of scent marks relative to vocalizations, but it is an area that is receiving a lot of research. So far, scent marks appear to have the potential to reveal a lot of information about the individual that placed the mark. Lemurs have received the most research with studies showing that sifaka secretions signal sex, season, and genetic relatedness, meaning that

the signals of closely related individuals are more similar than those of more distantly related individuals (Morelli et al. 2014). Similarly, ring-tailed lemurs secrete scents which vary by individual (Scordato et al. 2007), season (Scordato et al. 2007), and genetic relatedness (Boulet et al. 2009). Scent signals appear to be important for mate choice. Male ring-tailed lemur scent marks have been shown to convey information on genome-wide heterozygosity of the signaler, which itself correlates with health and survivorship, making it a useful signal for mate choice (Charpentier et al. 2008). Female signals also provide important information, varying according to whether they are pregnant (Crawford and Drea 2015) or on hormonal contraception (Crawford et al. 2011). Relative to the lemurs, much less work has been done on the other prosimians species. Early work on greater galagos showed that thick-tailed galagos use scent marks to discriminate between the sexes, evaluate reproductive state (Clark 1982a), and differentiate between individuals (Clark 1982b). Both thick-tailed galagos and Garnett's greater bush baby discriminated between their own and the other species (Clark 1988).

While the above studies largely focused on the information content of scent marks, either through examining whether the chemical composition varies by individual, species, etc. or by examining whether the animals respond differently to scents from different individuals, species, etc., another subset of studies has begun to investigate the how scent marks are used. For example, recent work has shown that wild spectral tarsiers scent mark primarily for territory defense, not to monitor the reproductive state of females (Gursky-Doyen 2010). Tarsiers marked most often along territory borders, more frequently on nights with territory disputes, and more often during the dry season when resources were scarcer than in the wet season (Gursky-Doyen 2010). They did not mark more often during the mating season than the non-mating season (Gursky-Doyen 2010) as would be expected if scent marks were used to monitor female reproductive state. Similarly, mouse lemurs are more likely to scent mark when leaving a sleeping site than when reuniting at a sleeping site suggesting that the marks were important for maintaining

spacing between sleeping groups and access to sleeping sites (Braune et al. 2005).

Interestingly, the slow lorises also secrete chemicals, but these secretions are specialized for defense (Nekaris et al. 2013). The loris mixes oil from its brachial arm glands with saliva to produce venom which it rubs on its own fur (Nekaris et al. 2013). This venom is strong enough to induce shock and death in small mammals (Nekaris et al. 2013). The main functions are thought to be for defense against parasites and other lorises (Nekaris et al. 2013).

## Multimodal Communication

While most work on prosimians communication has focused on vocalizations and scent marks individually, recent work has emphasized that these modalities work together. For example, ring-tailed lemurs were shown to be able to match the scents and vocalizations of individuals (Kulahci et al. 2014). Similarly, not only do species using glandular scent marks emit olfactory signals, but these signals are also multimodal (Scordato et al. 2007). The individual depositing them often does so with conspicuous visual or auditory cues (Scordato et al. 2007). Visual cues include handstands to deposit anogenital marks or elaborate movements such as the ring-tailed "stink fights" in which males anoint their tails with brachial and antebrachial secretions and then wave their tails at each other (Scordato et al. 2007). Auditory cues include scratching tree bark with an antebrachial spur during deposition (Scordato et al. 2007). Other group-mates may respond to this multimodal signal by investigating and adding marks of their own. Similar opportunities for combining sensor modalities occur when vocalizations or scent marks are paired with individually or species specific face markings, such as those occurring in several species of loris (Nekaris and Munds 2010) and galago (Bearder 1999).

## Conclusion

Prosimians have multimodal communication systems in which they combine auditory, olfactory,

and visual signals to convey information about who they are and to navigate social interactions. These communication systems are complex enough to communicate information about their species, sex, individual identity, kin group, and reproductive status during interactions relating to dominance, territorial displays, mate choice, and raising young. These signals are also flexible to enable communication during day or night, through dense forest, and to individuals both within a cohesive social group and to others in a dispersed social network.

## Prosimian Diets

Francis Cabana

Nocturnal Primate Research Group, Oxford  
Brookes University, Oxford, UK  
Wildlife Nutrition Centre, Wildlife Reserves  
Singapore, Singapore, Singapore

Due to their smaller size, lower metabolic rates compared to haplorhines, and adaptation to vertical strata, prosimian diets are highly specialized and range between purely insectivorous and purely leaf

eating. Sympatric *Cheirogaleus medius* and *C. major* have a diet of mostly fruits, followed by flowers, insects, and tree gums. Their foods are high in fiber, averaging 45.2% nitrogen detergent fiber (Lahann 2007). They reduce competition with other species by foraging at different heights with *C. medius* lower down and *C. major* higher up. Their diets are seasonal and select fruit during the weight gain season, to last through the following periods of hibernation. *Microcebus murinus* also has a varied diet of fruits, flowers, insects, and gums, which is highly seasonal and quite different depending on the field site (Dammhahn and Kappeler 2010; Lahann 2007). Gum is a major food source during particular seasons (Thoren et al. 2011). *Microcebus rufus*, being smaller in size, supports itself with fruits and insects and specifically the fruit of *Bakerella* spp. (Atsalis 1999). This is typical of many small-sized prosimians. The smaller *Microcebus berthae* ingests a larger proportion of insects and also ingests insect secretions which reduce the seasonal fluctuation in diet (Dammhahn and Kappeler 2008). This technique is also employed by *Microcebus ravelobensis* which also ingests insects, gum, and fruit (Thoren et al. 2011). *Mirza* spp. are omnivorous and eat fruits, leaf buds, insects and their secretions, tree gums, and also some small vertebrates when available. *Allocebus* spp. are mostly insectivorous but were also observed licking twigs or bark which may have contained some sap, secretions, or exudates such as gum (Biebouw 2013). *Phaner* spp. are an extreme, ingesting mostly gum with a small compliments of insects (Charles-Dominique 1977). At another extreme is *Daubentoniidae madagascariensis* which ingests largely insects, specifically grubs, which it can find burrowed in tree trunks (Pollock et al. 1985). They also ingest some plant matter such as the fruit and seeds of *Canarium* spp.

The larger bodied lemurs also have varying and seasonal diets. *Indri indri* are folivorous; however, they have been observed ingesting some other plant parts depending upon their location and probably have an important amount of seed ingestion (Powzyk and Mowry 2003). Young leaves are around 73–80% of feeding time, 7% mature leaves, and 5–8% fruits and a combination

of bark and petioles (Britt et al. 2002). Other leaf eaters include *Avahi laniger* and *A. meridionalis* which eat a mix of young and old leaves. *A. meridionalis* are also able to diversify their diets to flowers during the growing season. Naturally, their diets are quite high in fiber which is similar throughout the prosimians (Norscica et al. 2012). *Avahi occidentalis* have a broader diet, feeding from 25 trees and 5 lianas, feeding on mostly leaves (77% of feeding time) with fruits and flowers also being eaten (Thalmann 2001). *Propithecus* spp. are similar, with *Propithecus diadema* being entirely plant eaters ingesting flowers (3–25%), fruits and seeds (22–65%), and young leaves (28–53%) (Overdorff and Strait 1998; Powzyk and Mowry 2003). *Propithecus verreauxi* and *Propithecus tattersalli* ingest between 25% and 46% leaves, 33% and 65% fruit, and 9–10% flowers based on feeding time (Richard 1978). The well-known *Lemur catta* are extensive generalists and opportunistic omnivores which spend equal time on fruits and leaves (Sauther et al. 1999). Specifically spending 25–58% of feeding time on leaves, 34–70% on fruits, and 2–8% of flowers with animal matter being ingested from time to time (Sussman 1974). *Eulemur* spp. are also generalists but supposedly described as frugivores. *Eulemur fulvus* ingests a diet of mostly leaves or fruits depending on the season (Sussman 1974). *Eulemur rubriventer* and *Eulemur coronatus* are much more frugivorous and only ingest up to 13.6% leaves with fruits sometimes being 100% of their foraging time (Overdorff and Strait 1998). *Eulemur macaco* and *Eulemur mongoz* have similar diets; however, only *E. mongoz* has been reported to ingest nectar more prominently (Colquhoun 1993). Similarly, *Varecia* spp. are largely fruit eaters with 70–90% of their diets being fruit, with leaves, flowers, and nectar being a seasonal part of their diet based upon availability (Ratsimbazafy 2002). The *Hapalemur* (*Hapalemur griseus*, *Hapalemur simus*, and *Hapalemur aureus*) are specialized on ingesting bamboo leaves, except for *H. aureus* which also enjoys foraging in reed beds (Eppley et al. 2011; Glander et al. 1989). Each species prefers different parts of the bamboo and some are specific for particular species. *H. griseus*

ingests 88% bamboo and minor other grasses, preferring young leaf bases. *H. aureus* is similar, however prefers giant bamboo which is 78% of its feeding time and some other bamboo species and fruits. The strictest diet is that of *H. simus*, with giant bamboo being 95% of the diet, eating both mature and immature leaves (Grassi 2001). *H. griseus* has been known to also ingest soil and fungi, with the diet being quite seasonal (Grassi 2001). Only *H. griseus alaotrensis* is described as eating 100% leaves (Randrianarisoa 1999). Other leaf eaters include the *Lepilemur* spp. which are less catholic in their choices of food than the previous Hapalemurs. *Lepilemurs* select their food based on the nutrient concentrations, allowing for a large variety of food items throughout the seasons (Thalmann 2001). *Lepilemur ruficaudatus* and *Lepilemur edwardsi* spend 75% of their foraging time on leaves and 25% on fruits, buds, and flowers, with coprophagy also having been observed (Thalmann 2001). Leaves were the main food of *Lepilemur leucopus*, spending 91% of its foraging time eating them and the rest on fruits, tree gum, and some bark.

The Lorisiform prosimians are generally smaller bodied and nocturnal. This allows for a specialized feeding of insects and tree gums, more so than any other mammalian group. With diets varying between insects, fruits, and gums, body size is generally able to dictate their general diet. Medium-sized *Perodicticus potto* are largely fruit eaters, while the smaller *Arctocebus calabarensis* are described as more insectivorous (Charles-Dominique 1977). This trend continues with the small-bodied *Loris* spp. who are either entirely insectivore (*Loris tardigradus*) or mostly insectivorous with minor amounts of gum and legume pods (*Loris lydekkerianus*) (Nekaris and Bearder 2007). This is to the contrary of the Asian slow lorises (*Nycticebus* spp.), which are largely exudativorous. The smallest *Nycticebus pygmaeus* has a diet of approximately 30% gum, 30% nectar, and 40% insects (Starr and Nekaris 2013). Their smaller size does not allow for sufficient fermentation of gums for their energy, insects and nectar are necessary for denser energy. The larger *Nycticebus coucang* has a more varied diet of fruits, insects, and tree gum in larger

proportions than its smaller cousin (Wiens et al. 2006). The larger *Nycticebus javanicus* has a diet mostly of gum and insects, but also ingests a small amount of fruits, nectar, flowers, and leaves which is a transition based on their larger body size (Cabana et al. 2017). The largest of the Asian slow lorises is *Nycticebus bengalensis*, which has a highly fermenting diet of 96% gum and some insects and leaves (Das et al. 2014).

The bushbabies are a group of nocturnal primates varied morphologically but also in size and ecology. The smaller *Galago zanzibaricus* and *Galago senegalensis* are largely insectivorous, ingesting up to 70% insects, with some fruit and gum (Harcourt and Nash 1986). Gum is particularly important to the diet of *G. senegalensis* which can feed on it for up to 30% of its feeding time. This is similar to *G. moholi* which spends up to 48% of their time on gum and 50% on insects (Nekaris and Bearder 2007). The larger *Otolemur garnettii* and *Otolemur crassicaudatus* are able to ingest more gum (40%) and insects (40%) due to their size, with *O. garnettii* also relying on seasonal fruits (Harcourt and Nash 1986; Nekaris and Bearder 2007). Depending on the field site, *O. garnettii* was also described as highly insectivorous, having a diet 50–55% of animal matter, specifically insects and molluscs (Masters et al. 1988). The *Galagoides demodivii* and *cocos* have a highly insectivorous diet of 70% insects and 30% fruits (Charles-Dominique 1977; Nekaris and Bearder 2007). *Galagoides alleni* spent its time equally on animal matter and fruit. *Euoticus elegantulus* is the most exudativorous of the bushbabies, with only 20% of time spent on animal matter.

All of the diet information reported in this chapter is based on the percentage of time spent on foraging or feeding, therefore the percentages reported do not directly reflect the intake. Especially for insects and nectar, the ingested amount is often much lower than the feeding percentage and fruits tends to be higher (Cabana et al. 2017).

## Prosimian Life History

K. Anne-Isola Nekaris

Nocturnal Primate Research Group, Department of Social Sciences, Faculty of Humanities and Social Sciences, Oxford Brookes University, Oxford, UK

### Synonyms

Galago; Lemur; Loris; Potto; Strepsirrhine; Tarsier

### Definition

Life history characteristics include gestation period, size and number of offspring, lactation period, size at birth and age at weaning, pattern of postnatal growth, size and age at sexual maturity, interbirth interval, and lifespan (Martin 2008).

## Introduction

The Order Primates is made up of two unique suborders, the Haplorhini and Strepsirrhini, characterized by life history (including gestation, birthing patterns, weaning, and dispersal) patterns that are among the slowest of the mammals (Campbell et al. 2011). The prosimians comprise a polyphyletic clade including the haplorhine Tarsiiformes and the strepsirrhine Lemuriformes and Lorisiformes. Although the Tarsiiformes are more closely related to monkeys and apes, their nocturnal life style, habitat selection, and communication systems mean that aspects of their life history allows for interesting comparison with other Strepsirrhini, and for discussion of the evolution of these traits within the Order Primates. Because primates are long-lived, data for these traits often come from more common species in captive populations as collecting accurate data in the wild can take up to 50 years of study to understand these parameters even in a single population (Martin 2008; Fleagle 2013). In this entry, I summarize current knowledge of key life history traits across the three infraorders comprising the prosimians.

### Infraorder Tarsiiformes

Tarsiiformes (hereafter tarsiers) are comprised of three genera and 13 species. They are restricted to Borneo, Sumatra, Sulawesi, and surrounding smaller islands. *Cephalopachus bancanus* from Borneo and Sumatra seems to exhibit a noyau (solitary) social organization; little is known about *Carlito*, although they may be similar to *Cephalopachus*. In the better-studied genus *Tarsius*, uni-male, uni-female social units are common, characterized by duetting; within these units, however, more than one adult of either sex can occasionally occur. Ranging in size from 98 to 135 g, tarsiers have a gestation period of about 180 days. Tarsiers give birth to singletons; despite having three pairs of mammae, no multiple births of tarsiers have been recorded. Infants are large, typically 20–33% of the adult body weight. The

mother carries her young in her mouth and parks it for about half an hour at a time as she forages. Development of the young is rapid, and within 100 days they can forage self-sufficiently. The lactation period is on average 78–120 days. Adult weight tends to be reached at 8–10 months. Dispersal data are only available for *Tarsius spectrum*; both males and females disperse from their natal range, settling within 500 m of their original range. Captive individuals have been known to live for 17 years (Gursky 2004).

### Infraorder Lemuriformes

Lemuriformes comprises five families, the Cheirogaleidae, Lepilemuridae, Lemuridae, Indriidae, and Daubentoniidae. The Cheirogaleidae (hereafter cheirogaleids) include six genera and 19 species, the Lepilemuridae (hereafter sportive lemurs) include four genera and 13 species, the Lemuridae (hereafter lemurids) include four genera and 13 species, the Indriidae (hereafter indriids) include four genera and 13 species, and the Daubentoniidae (hereafter aye ayes) include four genera and 13 species. This radiation of primates is restricted to Madagascar and some small surrounding islands (Cavallini 2009).

Cheirogaleids comprise five genera and 31 species. Most species studied until now exhibit promiscuous mating systems. Ranging in size from 30 to 460 g, cheirogaleids have a gestation period ranging from 54 to 70 days. Perhaps due to their small size and high predation pressure, cheirogaleids give birth to litters of 2–3 young up to twice a year. Infants are kept in a nest or in tree tangles. They are carried in the mouth when they are young, but as they grow older they are able to cling to or follow the mother. The lactation period is on average 42 days. Members of the genus *Microcebus* can reach full sexual maturity at 8–10 months. Social patterns are diverse within this speciose family, with dispersal possible in either sex or being biased to one sex. Captive individuals have been known to live for 18 years (Fietz 1999).

Sportive lemurs comprise one genus and 26 species. Most of these species remain unstudied in the wild, with most data coming from

*Lepilemur ruficaudatus* and *L. sahamalazensis*. Although they are often described as solitary, there is evidence for multiple types of social units within this genus ranging from noyau to uni-male uni-female to dispersed family groups. Ranging in size from 700 g to 1.0 kg, sportive lemurs have a gestation period ranging from 120 to 150 days. Breeding tends to be seasonal depending on the region of Madagascar; the genus typically gives birth to singletons. Infants are kept in a tree hole or in tree tangles. When moved, the mother carries the infant in her mouth and keeps it in a tree nearby to where she is foraging. There is no evidence for paternal care in the genus. The lactation period is on average 75–120 days. Sexual maturity occurs at about 1.5–2 years. No evidence is available on longevity of this taxon.

Lemurids comprise five genera and 21 species. Social organization is diverse and include uni-male, uni-female groups; multi-male, multi-female groups; and single-male multiple-female groups. Ranging in size from the 800 g to 3.8 kg, lemurids have a gestation period ranging from 99 to 150 days; young of a size of 60 g have been reported. Most lemurids give birth to singletons, although twins can occur (Gould et al. 2003). The major exception is the genus *Varecia*, which can give birth to up to five infants. In the case of *Varecia*, infants are kept in a nest, whereas all other lemurids sleep in groups, and infants are huddled among the adults. Although *Varecia* may carry infants in the mouth, all other taxa exhibit fur grasping and riding on the dorsum or ventrum. The lactation period is consistently reported at about 6–7 months for all genera. In the best-studied *Lemur catta*, infants reach complete independence at 6 months, whereas in *Eulemur flavifrons*, sexual maturity does not occur until 20 months. A number of taxa are reported to reach 30–35 years in captivity; wild data from *L. catta* report one individual reaching 20 years.

Indriids comprise three genera and 19 species. The smaller indriids range from 1 to 6.8 kg, with *Indri* being the largest living lemur, reaching up to 9 kg. Group sizes range from small cohesive family units to large multi-male multi-female groups. Sexual maturity is reached at about 2.5 years in

*Propithecus* but not until 7–9 years in *Indri*. Indriids have a gestation period ranging from 120 to 176 days; breeding appears to be highly seasonal, with some species only able to mate on one day per year. Indriids typically give birth to one young, and in some cases inter-birth intervals are as long as 1.7 years. Infants are carried by the mother on her back or on her belly and become independent at about 4 months. All group members associate with and play with infants. The lactation period averages 240–300 days. Infants of *Indri* are born black and change to adult color at 4–5 months. Among *Propithecus*, infant mortality is described as high, including heavy predation from the fossa (Carnivora: *Cryptoprocta ferox*). In the case of *Propithecus diadema*, wild individuals of 20 years have been observed, and in the case of *P. edwardsi*, one wild individual obtained the age of 27 (Pochron et al. 2004).

Aye ayes comprise one genus and one extant species. Its social organization is multi-male, multi-female, and during estrous a female can mate with up to six males. Ranging in size from 2.4 to 2.6 kg, aye ayes have a gestation period ranging from 164 to 172 days. Single offspring are born any time of the year; unlike most other lemurs aye ayes are not seasonal breeders. Infants are typically born at 90–140 g. Infants remain near the nest until they are about 3 months old. The mother carries young in her mouth for about the first 3 months, until locomotor independence is achieved. The lactation period is on average 170 days. The young become independent at 18–24 months. Interbirth interval is long, with one young being produced every 2–3 years. In captivity, individuals have reached 24 years of age (Kappeler 1998).

### Infraorder Lorisiformes

Lorisiformes comprises two families, the Galagidae and the Lorisidae. The Galagidae (hereafter galagos) include six genera and at least 19 species, whereas the Lorisidae (hereafter lorises) include four genera and at least 13 species.

Galagos are distributed throughout Sub-Saharan Africa. Most species studied until now live in multi-male, multi-female social units, although several taxa also exhibit uni-male, uni-

female social units. Ranging in size from 35 g to 1.8 kg, galagos have a gestation period ranging from 110 to 135 days. With the known exception of *Otolemur crassicaudatus*, which regularly gives birth to twins, galagos typically give birth to one young; although twinning occurs in other taxa, data from the wild suggest that survivorship is low (Bearder and Doyle 1974). Infants are typically born less than 8% of the parent's body weight. Infants are kept in a nest or in tree tangles. When moved, the mother carries them in her mouth and parks them in a tree nearby to where she is feeding. The lactation period is on average 70–150 days. Adult weight tends to be reached at 8–10 months. In some taxa such as *Galago moholi* and *G. senegalensis*, females are philopatric and stay with their mother or establish a neighboring range, whereas in uni-male, uni-female genera like *Euoticus* and *Otolemur*, both sexes tend to disperse from their natal range at about 10–14 months. No wild data are available for the life span of galagos, but captive individuals have been known to live for 12–16 years.

Lorises include a Sub-Saharan African subfamily (the pottos of the Perodicticinae) and the slow and slender lorises of south and south-east (Lorisinae). Until now, all species studied exhibit uni-male, uni-female social units, although variability can occur within a single population (e.g., *Loris* – uni-female, multiple male; *Nycticebus pygmaeus*, uni-male, multiple female). Ranging in size from 110 g to 2.5 kg, lorises have a gestation period ranging from 157 to 205 days. With the exception of *N. pygmaeus*, where twinning is the norm, and *L. lydekkerianus*, where twinning comprises about half of births, lorises typically give birth to one offspring; although twinning occurs in other taxa, data from the wild suggest that survivorship is low (Weisenseel et al. 1998). Infants are typically born less than 5% (lorises) to 20% (pottos) of adult body weight (Charles-Dominique 1977). Lorises do not use tree holes, and the mother regularly carries infants after birth, clinging to her fur. When they are a few weeks old, the mother parks them near her foraging site or at the sleeping site. Adult males and older siblings regularly visit, feed with, and play with parked infants. The lactation period is on average

120–200 days. Adult weight tends to be reached at 8–10 months. In all taxa studied so far, both males and females disperse from their natal range at about 18–20 months (Nekaris 2003). No wild data are available for the life span of lorises, but captive individuals have been known to live for 18–26 years.

Overall, prosimians comprise a diverse group of primates. Despite their relatively small body sizes, they are characterized by slow life histories. Across all taxa that have been studied, there is evidence for social learning in regards to food and habitat selection and social behavior between offspring and parents over their relatively long period of development. It is the long lives of these animals that still means much more is to be learned about the very basics of life history of more than two third of the described taxa.

## Definition

Anthropoid

Primate group including Old World monkeys, New World monkeys, and apes. Largely diurnal, arboreal (but many species are terrestrial), and larger-bodied.

|                |                                                                                                                          |
|----------------|--------------------------------------------------------------------------------------------------------------------------|
| Cantilever     | A method of locomotion where the hind limbs are fixed to a tree branch to support the upper body in reaching activities. |
| Locomotion     | The movements and postures used by any animal.                                                                           |
| Prosimian      | Primate group including lorises, galagos, lemurs, sifakas, and tarsiers. Largely nocturnal, arboreal, and small-bodied.  |
| Quadrupedalism | A form of locomotion where all four limbs are used to move horizontally across a substrate.                              |

## Introduction

Locomotion encompasses the movements and postures that vertebrates use in day-to-day activities, especially in obtaining food, avoiding predators, and finding mates. Primates are specialists at arboreal locomotion and specifically at navigating life in the trees among small branches (Sussman 1999; Ankel-Simons 2007; Fleagle 2013). Among mammals, primates are remarkable in having an unusually high range of locomotor behaviors. They leap, walk quadrupedally, suspend from branches using their tail or feet, brachiate, climb, cling, and cantilever (Fleagle 2013). Despite this large range of locomotor behaviors, primates have relatively few postcranial morphological specializations that reflect these locomotor niches.

Grasping hands and feet with a divergent first digit (the first digit being called the “pollex” in the hand and the “hallux” in the foot) are one of the defining morphological adaptations in primates linked to the arboreal lifestyle (Cachel 2015). Unlike other mammals primates have nails instead of claws which support the soft tissue tactile ridges (dermatoglyphics) present on the digits. All primates (humans included) possess these dermatoglyphic patterns on the palms of their hands and soles of their feet (including at the end of the digits, i.e., fingerprints). The papillary ridges of

the hands and feet provide a source of friction during locomotion and object manipulation. Some primates also possess dermatoglyphic patterns on the skin of other organs. The distal third of the ventral surface of the prehensile tail of ateline monkeys is marked by a friction pad replete with papillary ridges (Organ 2017; Organ et al. 2011), which functions to provide sufficient friction during tail-assisted locomotion. The tarsier *Tarsius bancanus* also possesses a friction pad on the tail, although in this case it is located on the ventroproximal aspect of the tail and is used to prop the body during vertical clinging and resting activities (Sprankel 1965).

Lastly, primates are unique among mammals in the structure of the eyes and the bony components of the skull that holds the eyes. Non-primate arboreal mammals, such as squirrels, have eyes located on the sides of the head. Primates have both eyes situated at the front of the skull in an arrangement called “orbital convergence” (Ankel-Simons 2007; Fleagle 2013). This allows for overlapping visual fields and binocular (stereoscopic) vision. Living a successful arboreal lifestyle high in the forest canopy with thick vegetation is tied to accurate three-dimensional vision, which is necessary for locomotor planning (think about leaping from branch to branch high off the ground) as well as catching insects. Binocular vision allows for this three-dimensional vision.

Primates can be broadly organized into two groups (Fig. 1). The prosimians (“pre-monkeys”) consist of lorisiforms, lemuriforms, and tarsiers. They are considered to be the more “primitive” group of primates and more representative of what the earliest primates may have looked like. They also are considered good models of how the earliest primates may behaved because the fossil record indicates that the earliest primates were morphologically similar to tarsiers or galagos, thus likely arboreal (Sussman 1999; Covert 2002; Cachel 2015). Anthropoids (Old World monkeys, New World monkeys, and apes) are considered to be more “derived” than prosimians.

This entry provides first a summary of the prosimians, who they are, what they look like, how they live, and how they behave, and then moves

**Prosimian Locomotion,**

**Fig. 1** The classification of the order Primate into prosimians and anthropoids, with major defining characteristics of each group

into the factors that influence development of particular locomotor styles. Lastly, this entry provides a summary of the types of locomotion within the prosimians with illustrations of each type.

### Prosimian Lifestyles

Prosimians include the lorisiforms, lemuriforms, and tarsiers (see Fig. 2). Lorisiforms include the Asian lorises (slow lorises and slender lorises), African lorises (pottos and angwantibos), and galagos (bush babies). Slow lorises (*Nycticebus* spp.) and slender lorises (*Loris* spp.) are widely distributed in southern India, Sri Lanka, and throughout much of Southeast Asia (Nekaris and Bearder 2007). Pottos (*Perodicticus* spp.) and angwantibos (*Arctocebus* spp.) are found through much of central Africa (Nekaris and Bearder 2007). Galagos (*Euticus* spp., *Galago* spp., *Galagoides* spp., *Otolemur* spp., and *Sciurocheirus* spp.) are scattered throughout eastern, southern, and central Africa (Nekaris and Bearder 2007).

Lemuriforms are found only on the island of Madagascar and include the aye-aye (*Daubentonia* spp.), indriids (*Avahi* spp., *Indri*

spp., and *Propithecus* spp.), bamboo lemurs and lemurs (*Eulemur* spp., *Hapalemur* spp., *Lemur catta*, *Phaner furcifer*, *Varecia* spp.), mouse lemurs and dwarf lemurs (*Allocebus* spp., *Cheirogaleus* spp., *Microcebus* spp., and *Mirza* spp.), and sportive lemurs (*Lepilemur* spp.) (Gould and Sauther 2007). The tarsiers (*Carlito* spp., *Cephalopachus* spp., and *Tarsius* spp.) are found in the Philippines and the islands of Southeast Asia (Shekelle et al. 2010). While their phylogenetic affinities are debated (Hartig et al. 2013; Kumar et al. 2013), they are grouped here with the lorisiforms and lemuriforms on the basis of their behavior, ecology, and some morphological features.

While there is great diversity within the prosimians, they can be described as sharing several fundamental behavioral and morphological characteristics to the exclusion of anthropoids (Fig. 1). Prosimians are almost exclusively nocturnal and arboreal (Sussman 1999); ring-tailed lemurs (Fig. 3) and sifakas (Fig. 4) are the only prosimians that spend any regular time on the ground (ring-tailed lemurs spend up to 30% of waking time on the ground but sifakas come to the ground with less frequency), and, as shown in Fig. 2, they are two of the very few diurnal prosimians (Fleagle 2013).

| Infraorder                                  | Lorisiformes                                                                                                                                 |                                                                                                                                                                     | Lemuriformes                                                                                                                         |                                                                                                                          |                                      |                                                                                                        |                                         | Tarsiiformes     |

**Fig. 3** Ring-tailed lemurs (*Lemur catta*) in a terrestrial quadrupedal stance. Ring-tailed lemurs are the only prosimian group that routinely spend lengths of time on the ground. Note the divergent first digit on the hand and foot, helpful in maintaining a grasp on small tree branches (Photo credit Hajarimanitra Rambeloarivony)

Life in an arboreal environment does not typically support large social groups (see Liebal et al. 2013). Correspondingly, most prosimian species live in groups where sizes range from 2 to 3 individuals up to 12 individuals. The terrestrial ring-tailed lemurs (*L. catta*) are noted for consistently having large groups, sometimes in excess of 25 individuals, with a relatively complex social hierarchy system and a heavy reliance on stink bomb warfare (Gould and Sauter 2007; Liebal et al. 2013).

Prosimians have a smaller brain size: body size ratio than anthropoids, which may be related to their heavier dependence on olfaction and less dependence on vision in social communication. They also tend to have a smaller body size relative to anthropoids, which is likely related to development of locomotor styles (Ankel-Simons 2007; Liebal et al. 2013).

### Body Size and Locomotion

Locomotor behavior is influenced by numerous factors such as diet, social behavior, and skeletal morphology. However, body size is perhaps the most influential factor in locomotor style (Merritt 2010). Small mammals tend to be prey more often than predator. This in turn may push some small mammals to be nocturnal rather than diurnal, a mechanism for “hiding” from some predators. Being an arboreal mammal can also be a means of hiding from predators, with some

notable exceptions such as snakes (Merritt 2010).

Small mammals, weighing less, can often inhabit arboreal environments that would only support a relatively low body weight, such as thin, narrow branches (the so-called fine branch arboreal niche). Combined with increased avoidance of predators, a small body size is typically associated with arboreality in primates, many of whom are found within Prosimii (Fleagle 2013). Only the larger prosimians, such as the ring-tailed lemurs (Figs. 2 and 3) and sifakas (Figs. 2 and 4), routinely spend time on the ground out of the trees. While still subject to some predation, these larger prosimians are not subject to predation pressure as intensely as the smaller prosimians (Sussman 1999).

Lastly, body size has an important influence on dietary requirements in mammals. Smaller mammals have higher metabolisms than larger mammals and tend to need a higher quality diet with greater percentages of protein relative to larger mammals (Merritt 2010). Protein is typically represented in the form of other animals such as insects, young birds/eggs, and small reptiles. These food sources may be rare in any given arboreal environment and typically are not eager to be prey items so they may have to be chased and captured. Within primates this type of food is often associated with fast styles of locomotion such as leaping, hopping, or running. Larger mammals have slower metabolisms than small mammals and can afford to subsist on relatively

**Prosimian Locomotion, Fig. 4** *Left Image:* sifaka (*Propithecus* spp.) performing a spectacular aerial leap across the forest canopy. These vertical clinging and leaping prosimians push off of the tree limb with their powerful

hind limbs and fly through the air. *Right Image:* group of sifakas hopping bipedally on the ground with upper limbs extended to the side (Photo credit Hajarimanitra Rambeloarivony)

low quality but plentiful foods such as leaves, which don't need to be caught. Within primates this type of diet is often associated with slower styles of locomotion such as arboreal quadrupedalism or slow climbing (Ankel-Simons 2007; Fleagle 2013).

### Ways to Get Around as a Prosimian, or Locomotor Styles

Locomotion among prosimians takes widely divergent forms (see Fig. 2). With increasing body size, the amount of climbing in prosimians increases and the amount of leaping decreases (with the vexing and obvious exception of sifakas, who make spectacular leaps at their large body size – Fig. 4). Among primates in general, locomotion can be classified into four major types: vertical clinging and leaping (VCL), quadrupedalism (both arboreal and terrestrial varieties), brachiation, and bipedalism. Many primates adopt a mix of these locomotor styles throughout their activity cycle, depending upon which substrate they are using at any given time and what the goal of their movement is (gathering food, agonistic encounters, predator avoidance, etc.). Within these four major types of locomotion, there are a number of subtypes, such as arboreal versus terrestrial quadrupedalism, and the differences between the categories lie primarily

in the degree to which the forelimbs versus hind limbs are used to climb, swing, jump, and run.

Small-bodied prosimians tend to be arborealists and exploit quadrupedalism and/or vertical clinging and leaping. The smallest prosimians tend to be committed vertical clingers/leapers and are the small galagos, weighing in at 50 g–450 g (*Galago*, *Galagoides*, *Sciurocheirus*), and the tarsiers, weighing in at 60 g–150 g (*Carlito*, *Cephalopachus*, and *Tarsius*), as shown in Fig. 5. The tiniest lemuriforms of Madagascar are the mouse lemurs weighing in around 50 g (see Fig. 2). These diminutive prosimians use both arboreal quadrupedal running and vertical clinging and leaping (Fig. 6), all occurring along the smallest branches of trees. This is a rare locomotion style for large prosimians. Sifakas (*Propithecus* spp.) are enormous among the prosimians, weighing in around 6 kg, well above the average house cat. These diurnal prosimians are vertical clingers and spectacular leapers (see Fig. 4). No doubt due in part to their large body size, sifakas spend time on the ground and employ a unique style of locomotion, bipedal hopping (Fig. 6).

### Vertical Clinging and Leaping (VCL)

This locomotor mode involves, as its name suggests, clinging to a relatively narrow vertical tree branch with both forelimb and hind limbs (e.g.,

**Prosimian Locomotion, Fig. 5** Tarsier (*Tarsius* spp.) clinging onto a tree branch in a typical posture. Tarsiers are categorized as vertical clingers and leapers. **Prosimian Locomotion, Fig. 6** A mouse lemur (*Microcebus* spp.) clinging onto a spiny tree in the spiny forest of Madagascar. These lemuriforms are among the smallest of the prosimians and use both vertical clinging and leaping and arboreal quadrupedalism (Photo credit Hajarimanitra Rambeloarivony)

see Fig. 5). Vertical clingers and leapers – typically small-bodied prosimians – largely avoid going to the ground by using long-distance, ricochet leaps to get from tree to tree. Using the hind limbs and powerful hamstring muscles, these primates push off of the vertical substrate and reach for the upcoming substrate with their forelimbs. VCL is a fast way of moving that can be helpful in avoiding predators and catching animal prey.

### Arboreal Quadrupedalism

The vast majority of primate species are arboreal (Fleagle 2013) and most prosimians adhere to this general rule (see Fig. 2). The conservation of quadrupedalism in primates is evident in examinations of the primate fossil record as well, with indications that the earliest primates included some quadrupedalism in their

locomotor repertoire as well (Larson 1998). Arboreal quadrupedalism is the preferred mode of locomotion for the larger galagos (*Otolemur* spp., Fig. 7), lorises (Fig. 8) and pottos and all lemuriforms except sifakas and sportive lemurs. Among the arboreal quadrupeds, slow lorises and slender lorises (*Nycticebus* and *Loris*) stand out for their remarkably slow method of advancement. While most of the small galagos and the tarsiers are rapid VCLs, lorises take an opposite approach.

Quadrupedalism in primates is somewhat different than in most other quadrupedal mammals. While many mammals move quadrupedally, primates do so using a high degree of forelimb protraction with a diagonal, couplet gait. This diagonal gait allows only one limb to be off the substrate at any one time, increasing contact on curved, narrow branches and proffering added

**Prosimian Locomotion,**

**Fig. 7** One of the larger galago species, *Otolemur crassicaudatus*, using arboreal quadrupedalism on a small branch. Note the grasping hands and feet in this galago as it moves along the branch (Photo credit Simon Bearder, Nocturnal Primate Research Group, Oxford Brookes University)

**Prosimian Locomotion,**

**Fig. 8** Upper image: slow loris (*Nycticebus coucang*) in preparation for a cantilever stance. Note the widely divergent lower limbs grasping onto small branches to support the rest of the body as the cantilever begins. Lower image: same slow loris from below in a full cantilever body. Note the fixed hind limbs and the forelimbs reaching ahead (Photo credit Andrew Walmsley, Little Fireface Project)

stability in the canopy (Larson and Stern 2006; Schmitt 1998; Schmitt et al. 2006).

Whether done in the trees or on the ground, primate quadrupeds tend to protract their upper limbs to a higher extent than other mammalian quadrupeds (Schmitt 1998; Schmitt et al. 2006).

Protracting the forelimbs may produce a longer stride, reducing the frequency of gait. This sort of gait pattern may be useful in reducing the branch sway during quadrupedal walking, thereby reducing the danger of falling off the branch and alerting potential prey. Primate quadrupeds also

use a diagonal gait or diagonal couplet where opposite forelimbs and hind limbs move together.

Lorises are among the most carnivorous of all primate species (feeding on insects and small reptiles). Instead of rapidly approaching their prey like carnivorous galagos and tarsiers, lorises tend to take a slow, stealthy approach. Lorises, especially slow lorises, are also remarkable in their use of cantilevering in moving through small branches. Cantilevering is a mechanism by which the hind limbs are fixed in grasping a small branch, while the rest of the body projects forward, not unlike a cantilevered beam (see Fig. 8).

### Terrestrial Quadrupedalism

Very few prosimian species come down from the trees to move quadrupedally on the ground, with the notable exception of *L. catta* (Fig. 3). The very small prosimians, such as tarsiers, mouse lemurs, and some galagos, prefer to stay in the trees which may provide some protection against predation. The larger *L. catta* spends almost a third of its waking time on the ground in a variety of activities. While there are no definitive explanations for why ring-tailed lemurs spend so much time on the ground, it may be associated with their highly complex social behavior and relatively large social groups. Ring-tailed lemurs are indeed preyed upon by fossae, raptors, boas, and civets but predation pressure varies from site to site. Functionally, terrestrial quadrupedalism is similar to arboreal quadrupedalism with the main difference being differences in substrate compliance.

### Bipedalism

The only prosimian that engages in any sort of routine bipedal locomotion is the sifaka (*Propithecus* spp.). Figure 4 shows a typical bipedal hopping bout in an adult sifaka. While these large-bodied primates are usually a VCL when in an arboreal setting, they come to the ground with varying frequency. Instead of using quadrupedal locomotion when terrestrial, they engage in a hopping behavior with their hind

limbs. Tails are typically extended along with the upper limbs at their sides.

## Conclusion

The focus of this entry was to provide a summary of prosimian diversity, including basic taxonomy, preferred habitats, and unique modes of locomotion employed to navigate those habitats. In brief, prosimians employ a wide range of locomotor repertoires including vertical clinging and leaping, arboreal and terrestrial quadrupedalism, and bipedalism. The preferences for locomotor style are directly tied to issues of body size, with smaller species occupying more arboreal habitats and employing more leaping and quadrupedal walking/running, whereas larger species occupy more terrestrial habitats and use combinations of quadrupedal and bipedal locomotion to negotiate their environments.

## Prosimian Morphology

Stephanie A. Poindexter

Department of Anthropology, SUNY Buffalo, Buffalo, NY, UK

## Synonyms

Galago; Lemur; Loris; Potto; Strepsirrhine; Tarsier

## Introduction

There is a wide range of unique morphological features present across prosimians. Some features are seen in each species, though others are seen only in a few. As the majority of nocturnal primates are prosimians, features such as the tapetum lucidum, which aids their vision during the night, a grooming claw on the foot, and a wet nose are universally present. Though, as in most cases there are exceptions to these generalized rules. Each prosimian is unique and distinguishable, giving way to their identification as separate families, genera, and species. Presented here are general morphological features grouped by the three infraorders included in the classification prosimian (Tarsiiformes, Lemuriformes, and Lorisiformes).

## Tarsiiformes

Tarsiiformes (tarsiers) classify of three genera and 11 species. Tarsiers are morphologically unique in that they display many features associated with both strepsirrhines and haplorrhines. They have a short trunk and a large head; they also lack a wet rhinarium, which places them among the haplorrhines. Their ears are hairless, round, mobile, and membranous; it is well understood that they have very acute hearing, and the terminal nuclei of the cochlear nerve is particularly large.

Tarsiers have the ability to rotate their heads almost 360°. They have large eyes, where a single eyeball is the same size as their brain and their eye sockets are only partially closed, compared to the fully closed sockets seen across primates. Unlike other nocturnal primates, this genus is exceptional, as they seem to lack a tapetum. Compared with other prosimians, it is clear that tarsiers are morphologically specialized for predatory functions; their auditory acuity and their comparatively reduced olfactory region support this theory. Regarding dentition, tarsiers are identified by the dental formula 2-1-3-3/1-1-3-3. Their postcranial morphology focuses on their vertical clinging and leaping locomotor specialization. Their intermembral index is about 56, the lowest among all primate species, which means that their hindlimbs are longer than their forelimbs, most notably they have an elongated tarsus, which is reflected in their name. While resting in vertical postures, tarsiers can use their tails, which has a friction pad, to provide additional support. On their hands, the fingertips are enlarged and disc-shaped; they are also the only primates that have two grooming claws.

## Lemuriformes

Five families make up the infraorder Lemuriforme, Cheirogaleidae, Lepilemuridae, Lemuridae, Indridae, and Daubentoniidae. Cheirogaleidae (cheirogaleids) include six genera and 19 species, Lepilemuridae (lepilemur) include four genera and 13 species, Lemuridae (lemurids) include four genera and 13 species, Indridae (indriids) include four genera and 13 species, and Daubentoniidae (aye-ayes) include four genera and 13 species.

Cheirogaleids, which include both dwarf and mouse lemurs, range in body size from 19 to 27 cm and are among the smallest known primates. Compared to other Lemuriformes, they have a globular head, hairless ears, and a more elongated muzzle. Their postcranial morphology reflects their locomotor behavior and diet. In cheirogaleids, their hindlimbs are somewhat longer than their forelimbs but not as elongated as in vertical clingers and leapers. Their intermembral index averages at 71. They grasp substrates and

items using their second and third digit, instead of the more typical thumb and index finger grasp. They have keeled nails, which facilitates their ability to access saps and gums on vertical substrates. An extreme specialization within this group is the fat tailed dwarf lemur and its use of their tail to store fat during periods of torpor.

Lemuridae range in size between 28 and 60 cm, this includes the larger ruffed lemur to the smaller bamboo lemur. Morphologically lemurids possess specialization that facilitates a specific ecological or behavioral function. The bamboo lemur is able to consume levels of cyanide that would otherwise kill any other mammal (Glander et al. 1989). Wright and Randriamanantena (1989) suggested this specialization enabled multispecies sympatry in a single environment. *Lemur*, *Eulemur*, *Hapalemur*, and *Varecia* all have scent marking glands on their wrists, inside their elbow, and in the genital area, which are used as a form of communication, between individuals and different animals. Most Lemuriformes are arboreal and have hair covering their heels, except for *Lemur catta*, a terrestrial species that have hairless heels. All lemurs have a dental formula of 2-1-3-3/2-1-3-3 except for lepilemur who have a dental formula of 0-1-3-3/2-1-3-3 and aye-ayes who have a dental formula of 1-0-1-3/1-0-0-3.

Indridae is comprised of the largest extant lemurs, indris have a body length of about 70 cm; sifakas are about 45–54 cm long. Indriids have a specialized postcranial morphology; their hindlimbs are longer than their forelimbs with an intermembral index of 62. Indris are distinguished from all other genera of Madagascan prosimians by having very short tails and limbs designed for vertical clinging and leaping. Between the leaping indri and quadrupedal ruffed lemurs, their vertebral morphology is distinct, which highlights the importance of varying spine morphology as well as limb morphology in identifying locomotor specializations (Shapiro 1995).

Daubentoniidae is a highly specialized lemur species, known for its rodent like teeth and elongated third digit. Aye-ayes have a body length of about 40 cm and a tail that exceeds the length of their body. They have large eyes, large membranous ears, and a narrow muzzle. A series of

complex ridges on the inner ear allow the aye-aye to have an acute auditory sense, to hear insects and respond to their movement while series tree cavities. The cranial morphology of the aye-aye is easily identified by their reduced dentition and relatively large brain case. All four limbs are comparatively short, though the hind limbs are relatively shorter than the forelimbs. They have an intermembral index of 70 and unlike other lemurs, the aye-aye has claws on its hands and feet except on the big toe, they also have an elongated third digit used to tap along branches and trunks, which aid them as they feed on structurally defended resources (Sterling 1994).

### Lorisiformes

Two families make up the infraorder Lorisiformes, Galagidae (galagids), and Lorisidae (Lorisids). Galagidae include six genera and about 19 species and Lorisidae include four genera and about 13 species.

Lorisids, including all lorises, angwantibos, and pottos, all have a vice-like grip. They also possess a specialized vascular supply, which allow lorisids to maintain static positions for extended periods of time, called the *retia mirabilia*. Slender lorises range in body length between 18 and 27 cm. They have a round head, round ears, and large eyes. They have a narrow muzzle, especially in comparison to other prosimians. They have long thin limbs, which give them a slender appearance. The slow loris on the other hand is more robust; they have large limbs and a less elongated muzzle. They have a reduced tail and a reduced second digit on their hands. This digit morphology aids in the previously mentioned vice-like grip. *Nycticebus* not only has powerful hands but especially powerful grasping feet compared with the hands and feet of the slender loris. In the slow loris, the limbs are essentially equal lengths; thus, their intermembral index is about 89. Pottos range in length between 33 and 42 cm; much like the slow loris they have a reduced tail, though it is the longest among all Lorisids. Pottos have large eyes reflecting their nocturnality, but relative to other Lorisids they are somewhat small. They have an intermembral

index of about 88, where their hindlimbs and forelimbs are the same length, similar to the slow loris. Regarding their postcranial morphology, they have strong hands and feet specialized in grasping. Their second digit is extremely reduced enabling a more secure grasp between the thumb and third digit. On the foot the second toe has a grooming claw, which is not uncommon among prosimians. Perhaps the most fascinating morphological feature in this primate is the use of a scapular shield, as a defense mechanism. Their dorsal spine protrudes above the surface of the skin and when threatened an individual will curl its head under its shoulders and quickly throw their bodies forward in a punching motion. Angwantibos range in body length between 22 and 27 cm. Their head is quite similar to slender lorises in that they are globular with a narrow muzzle, though their ears are smaller and flatter in comparison. A trend among Lorisids they also do not have a tail, but Angwantibos are extremely unique in regards to their hand and foot morphology. Their index finger is reduced and is positioned opposite digits three to five in the hand. Digits four and five are webbed and the third digit is much shorter than both digits four and five. They also have webbed toes; digits three to five are webbed, similar to their hands.

Galagids, also known as bushbabies, range in body length between 29 and 47 cm and have large eyes, a globular head, and large membranous ears, which can move independent of each other. Bushbaby ears are relatively the largest ears of all primates. Galago skulls resemble those of lorises but differ slightly. They have a wider interorbital distance and a more rounded cranium. All bushbabies are vertical leapers and have been observed resting in upright position. Their hindlimbs are considerably longer than their forelimbs, as expected for a vertical leaper. Among galagos, their intermembral indices vary between 57 and 64. A unique feature among three species of bushbaby is their hand and foot morphology. The needle claw bushbabies have needle-like nails on the ends of most of their fingers and toes, to facilitate access to tree trunks as they eat gums and saps. As is the case in most prosimians, they have a grooming claw on the second toe, and the remaining digits just have nails.

## Conclusion

Prosimians are a large and diverse group of primates, which makes it difficult to succinctly describe all of the morphological characteristics that make them unique across the Order Primates and among each other. The characteristics discussed above are generalized across the families, within the three infraorders: Tarsiiformes, Lemuriformes, and Lorisiformes. Each family, genus, and species has a number of specific features that distinguish one from another. These features are seen in their pelage variation, genetic variation, and anatomical differences. This entry focused on general anatomical differences and their behavioral and ecological function. Many researchers have extensively studied morphological differences in living individual and preserved specimen. Thus, this entry can be supplemented by a number of historical and recent research articles and books that further detail the differences seen in prosimians.

## Prosimian Navigation

Stephanie A. Poindexter  
Department of Anthropology, SUNY Buffalo,  
Buffalo, NY, UK

## Definition

Navigation – the intentional act of determining and maintaining a route from one place to another (Gallistel 1990).

## Introduction

Prosimians are comprised of three infraorders: Tarsiiformes, Lorisiformes, and Lemuriformes. Few studies focus on prosimian navigation to the same extent as it is studied in other animals; instead aspects of navigation are incorporated into analyses of foraging and dispersal patterns. Call and Tomosello (1997) noted the limited amount of information on spatial cognition in prosimians, emphasizing that further research was needed to discover their capacity for negotiating their environment. Knowledge on this topic is continuously expanding and with an increase in dedicated research, new findings will shed light on the navigational capacity of these primates. Here I summarize findings on navigational behavior in prosimians including directed searches, such as, foraging patterns.

## Tarsiiformes

Researchers working on habitat utilization and behaviors clearly show that *Tarsus* species travel to goal locations and engage in exploratory movement and nonrandom use of their homeranges.

Path lengths in *Tarsius diana* of Kamarora fluctuated based on habitat disturbance compared to those in more pristine forests (Merker 2006), suggesting that these individuals are in search of specific resources lacking in the disturbed areas. *Tarsius syrichta* males frequently move along the periphery of their homerange and traveled from one end to the other, presumably to survey their territory. Females regularly followed the same path for several nights and then changed to a new travel path (Neri-Arboleda et al. 2002). Minimum nightly travel varies between species, where *T. syrichta* (260–556 m) travel less than *Tarsius bancanus* (Crompton and Andau 1987) and *Tarsius spectrum* (Gursky 1997; Dagosto et al. 2001). No studies on more complex navigational skills, including mental map use, are reported for tarsiers.

### Lorisiformes

Traveling and foraging make up as much as 50% of nightly activity in *Loris* species, where traveling is defined as directed movement (Nekaris 2001). Lorises traveled along the perimeter of their home ranges, for territorial purposes, similar to tarsier species. Males were also observed traveling in a direct line for more than 50 meters to reach female conspecifics (Nekaris 2001, 2003). *Nycticebus* species also display goal-oriented travel. The Javan slow loris likely uses route-based mental maps to navigate their environment. Other species of slow lorises possess many of the same feeding and behavioral characteristics as the Javan slow loris, thus likely use some form of mental representation, as well, to return to immobile resources, including parked infants (Fitch-Snyder and Ehrlich 2003). *Galago* species utilize gum, another immobile food resource, which requires nonrandom use of their homerange and directed travel to regularly find gum-producing tree and return to its location.

### Lemuriformes

Following a number of studies including Lemuriformes, all consistently report that they do not randomly move within their environment, a preliminary indicator of higher navigational skills. *Propithecus edwardsi*, *Eulemur fulvus rufus*, *Microcebus murinus*, *Eulemur rubriventer*,

*Eulemur rufifrons*, and *Varecia variegata editorum* all display nonrandom use of their environment, leading researchers to acknowledge that they utilized distinct routes when traveling from point A to point B (Everhart and Overdorff 2008; Lührs et al. 2009; Razafindratsima et al. 2014; Joly and Zimmerman 2011; Schliehe-Diecks et al. 2012). *P. edwardsi* and *E. f. rufus* uses “traditional” travel routes to get from one food patch to the next. Through the use of “traditional” travel routes, animals are able to check the status of various resources along the way as they move from one important food source to another (Milton 2000), particularly resources that are out of sight from their current location. Similar to *P. edwardsi* and *E. f. rufus*, *M. murinus*, *E. rubriventer*, *E. rufifrons*, and *V. v. editorum* all reused particular routes to travel between feeding resources (Lührs et al. 2009; Razafindratsima et al. 2014), where *E. rufifrons* displayed frequent backtracking behavior. Reusing the same routes and feeding locations suggests that these animals have some form of mental representation of their environment. How complex these representations are is a point of debate among those studying spatial cognition and can be difficult to determine outside of controlled experiments. *M. murinus* uses cues to successfully travel along routes and route overlap than compared to that of larger more social diurnal primates (Joly and Zimmerman 2011). While dispersing, this species moved in a straight line and covered many areas than during normal ranging patterns. Schliehe-Diecks et al. (2012) concluded that these unusual patterns were the result of a standardized exploration/dispersal strategy. Lemuriformes have been the focus of both basic and complex navigational research, providing a much more complete picture of how these species negotiates their environment.

### Conclusion

Navigation, or the act of using an intentional route to move from one location to the next, is seen across a number of animal species. In prosimians, basic navigational skills including foraging patterns and seeking conspecific are seen in all three infraorders. Research focused on more complex

navigation like mental mapping is limited to *Nycticebus* species and some Lemuriformes. Though spatial cognition is not a new topic and there is no limit to the amount of research focused on navigation in other animals, there is an emerging interest in expanding this research to include prosimians.

## Introduction

To successfully negotiate the challenges of living in a dynamic environment, animals generally can receive and interpret sensory information. This information includes visual, olfactory, auditory, tactile, and gustatory cues. Using their sensory system, they can discern dangerous situation, identify conspecifics, and locate food resources. Prosimians are a taxonomic group comprised of lemurs, lorises, galagos (strepsirrhines), and tarsiers. Unlike other primate taxonomic groups, the majority of nocturnal primates fall within the classification of prosimian. As such, there are varying ways that sensory cues inform these primates. Here I will focus on vision, olfaction, and auditory cues, as our understanding of the prosimian sense of touch and taste is limited.

## Vision

Vision plays an essential role in small-scale prey detection in nocturnal strepsirrhines (Bearder et al. 2002; Nekaris 2005). Experimental research suggests that there is little difference between nocturnal visual detection and that of sympatric diurnal species (Bicca-Marques and Garber 2004). Veilleux and Kirk (2014) measured the visual acuity of six strepsirrhine primates (*Cheirogaleus medius*, *Eulemur macaco*, *Galago senegalensis*, *Lemur catta*, *Microcebus murinus*, *Otolemur crassicaudatus*) concluding that both diet and diel patterns influenced the evolution of optical resolution in strepsirrhines.

Strepsirrhine eye morphology shares certain features that make them distinct from other primate taxa. Their retinas lack foveae (a small pit in the back of the retina) and have a lower cone/rod ratio, and their eyes often contain reflective tapeta. The tarsier (Tarsiidae) deviates from this pattern as a haplorrhine, despite being included as a prosimian. Tarsiers have incredibly large eyes relative to their body size and lack the tapetum lucidum that is typical in other nocturnal primates. The retinal foveae in tarsiers are variably reported, some report that they are universally present while others say it is absent in some individuals. Another point of departure from the strepsirrhine standard is the report of underdeveloped foveae occasionally seen in galagos (DeBruyn et al. 1980).

Generally speaking, strepsirrhine tend to be monochromatic or dichromatic, but some species show a population level polymorphism where some females are trichromatic. Dichromatic versus trichromatic color vision in primates is the result of variations in opsin genes that code for different classes of cone photopigments in the eye (Jacobs et al. 1996). Strepsirrhines have two types of retinal cones S (short wavelength-sensitive) and M/L (medium/long wavelength-sensitive), as is true in most mammals. This dual system facilitates dichromatic color vision between shorter (blues) and longer (greens/yellows/reds) wavelengths of light (Jacobs 2009).

Whereas dichromacy is retained in many lemurs, all loriforms (lorisids and galagos) have lost S cones due to deleterious mutations in specific opsin genes (Jacobs 2013). Species of lemurs exhibit variability in the peak spectral sensitivities of their M/L and S cones (Veilleux and Kirk 2009). In contrast, all loriforms seem to share the same M/L peak spectral sensitivities (Tan and Li 1999).

Polymorphism may be linked to behavioral trichromacy in heterozygous ruffed lemurs but there is no evidence of behavioral trichromacy in heterozygous sifaka (Leonhardt et al. 2008). They reported a modest effect of opsin polymorphism on behavioral trichromacy, mirroring the small shift in spectral sensitivity further suggesting that trichromacy may be only one of several routes toward increased foraging efficiency in visually complex environments.

## Olfaction

Many prosimian species use glandular secretions to engage in scent-marking. Through scent-marking behaviors, these species can use olfaction to communicate information about themselves including their health, reproductive stage, relatedness, and age.

The pygmy slow lorises (*Nycticebus pygmaeus*) during peak estrus showed a significant preference for counter marking males (Fisher et al. 2003). They suggested that the act of countermarking could signal continued competition and the counter marker could be perceived as the “winner.” In this situation, olfaction leads females to perceive counter markers preferentially; it also highlights how olfaction is used to delineate individuals. This research also supports the “competitive countermarking hypothesis,” and demonstrate that chemosignals play a profound role in governing female reproductive behavior in prosimians. In ring-tailed lemurs (*Lemur catta*), semiochemical profiles within and between males provided two types of genetic information (individual heterozygosity and genetic distance).

During the breeding season, male ring-tailed lemurs use their scrotal secretions to convey olfactory cues indicating their genetic distance and genetic quality. This represents another instance where valuable information about an individual during a time when male competition and female choice can have long-term consequences on fitness. Ring-tailed lemur females dampened their expression of volatile chemicals during pregnancy, and the compound richness is notably reduced in females bearing sons. Such olfactory signatures of pregnancy may help guide social interactions, potentially reducing intragroup conflict; cues that also advertise fetal sex may additionally facilitate differential energetic allocations based on sex. In an analysis of urine and nonurine chemical composition in a broad range of prosimians, urine markers expressed the most chemically complex and distinctive urine. More distantly related species had more variation in urinary profiles, suggesting gradual signal evolution (Delbarco-Trillo et al. 2011). It was further suggested that urine marking is an ancestral behavior related to solitary, nocturnal living and that parallel evolutionary shifts toward greater reliance on glandular marking, a derived trait occurred in diurnal and more social lemur genera.

Red-ruffed lemurs (*Varecia rubra*) use scent-marking to convey information about sex and female age, with male neck marking behavior serving a defensive territorial function and anogenital marking is used in sociosexual communication (Janda et al. 2019). There is also evidence to support that lemur species use olfactory indicators to signify naturally occurring injury. This is beneficial given the social and physical costs of injury; it is possible that lemurs are aware of the health status of conspecifics and are selective in who they engage in aggressive behaviors (Harris et al. 2018). In addition to communicating sociosexual information, olfaction plays an important role in interpreting environmental cues. Across the Order Primates, there is a variation in the number of functional olfactory receptor (OR) genes, which is associated with processing ecological olfactory cues. In haplorhines, there are 300–400 functional

genes, and in strepsirrhines, there are approximately 640 functional genes (Matsui et al. 2010; Niimura et al. 2014). Research on how prosimians use olfaction in an ecological context is emerging, including the following examples.

Lemur olfactory foraging behavior was negatively associated with fruit volatile organic compound (VOC) sums, whereas higher VOC sums showed a marginally significant negative association with how much an individual was observed sniffing a food item (Valenta et al. 2016). The authors concluded that items with a higher VOC did not require individuals to use olfaction as much as they would for items with a low VOC sum. The relationship between the olfactory cues emitted by fruits, insects, and other vegetation can act as another signal in which prosimians can use their sensory system to utilize their environment successfully. The authors also noted that it is likely that the overall smell signal is not the only predictor of olfactory foraging behavior.

Wooly lemurs (*Avahi*), a nocturnal folivore, engaged in more olfactory-based foraging when the visual signals of a leaf species were not conspicuous enough to discern young and mature leaves (Sawyer et al. 2019). This report in a nocturnal folivore emphasizes that the traditional notion of a trade-off between olfaction and vision is not a linear path by which nocturnal prosimians only use olfaction, and trichromatic haplorhines do not. As we dig further into the mutual and antagonistic relationship between vegetation and the species that feed on them, we will gain a better understanding of the role olfaction plays in the prosimian sensory system.

## Auditory

Across prosimian species, there is an extensive repertoire of audible vocalizations ranging from contact calls to alarm calls, used to communicate with conspecifics, as well as, high frequency and ultrasonic vocalizations which can be used to evade predators. Along with the ability to produce high-frequency vocalizations comes the

ability to hear at a higher frequency compared to other primates.

Primate auditory morphology varies along phylogenetic lines; in extant strepsirrhines, most lemurs have an unfused tympanic ring surrounded by a large, single-chambered middle ear cavity, whereas lorises have a tympanic ring that is fused to the lateral tympanic wall and exhibit a multi-chambered middle ear cavity (Cartmill 1975); the latter is also the case in haplorrhines. The shape of the pinna in strepsirrhines is generally relatively tall and narrow compared with that in haplorrhines (Coleman and Ross 2004).

Following an auditory brainstem response (ABR) analysis of 11 prosimian species (*Daubentonia madagascariensis*, *Eulemur coronatus*, *Eulemur fulvus collaris*, collared lemur *Eulemur fulvus rufus*, *Eulemur mongoz*, *Eulemur rubriventer*, *Lemur catta*, *Nycticebus coucang*, *Nycticebus pygmaeus*, *Propithecus coquereli*, *Varecia rubra*), Ramsier et al. (2012) found that social complexity and enhanced hearing sensitivity coevolved, and this relationship is a general biological pattern in other mammals. Given that larger social groups form in part to act as a deterrent for predation and that predator-specific alarm calls often have a high-frequency, it is reasonable that sociality is linked to the evolution of high frequency calls. This relationship between group size and high-frequency vocal sensitivity is a natural progression to what we see in some of the smaller bodied nocturnal prosimians. Tarsiers are the most notable case as a strictly insectivorous primate and are one of the only known primates that use pure ultrasound to communicate. Mouse lemurs also utilize ultrasonic communication (Zimmermann 2018). Reportedly, the Javan slow loris also used pure ultrasonic vocalizations. It is suggested that they use it as a form of contact call as they are solitary foragers (Nekaris and Geerah 2018).

## Touch and Taste

Relative to vision, olfaction, and auditory senses, tactile and gustatory sensory cues are

understudied. In regards to tongue morphology, there is little variation across primate species, though some prosimian species display a serrated sublingual. In addition, many prosimians appear to lack foliate papillae and have fewer circumvallate papillae. Strepsirrhines also have fewer taste buds in their circumvallate papillae compared to haplorrhines.

In humans, fungiform papillae density (FPD) is positively correlated with taste sensitivity; in strepsirrhine, sucrose sensitivity was negatively correlated with FPD, but positively correlated with the size of papillae among primates (Alport 2009). In addition, FPD was negatively correlated, and the papilla area was positively correlated, with the percent of fruit and flowers in a species' diet. These results suggest that strepsirrhines use their taste buds to discern different sugar levels and that there is a link between taste sensitivity and diet.

Black-and-white ruffed lemur individuals showed a marked preference for different sugars, where sucrose > fructose > glucose ≥ maltose ≥ lactose (Wielbass et al. 2015). The pattern of relative preferences for various sugars was similar in platyrrhine primates and humans, but differed from catarrhine primates. They concluded that their results support the idea that relative preferences for food-associated sugars in primates, but not necessarily their sweet-taste sensitivity, may correlate with diet.

Regarding prosimian touch, Erickson (1991) noted that in Aye-Ayes, the sense of touch likely played a role in foraging. They were observed to tap their third digit in an unexpectedly gentle fashion, suggesting that it serves a function in sensing surface vibrations. More research on this sense is needed to fully understand the role it plays in ecological and sociosexual success in prosimian species.

### Definition

*Pro-social behavior* is any voluntary action or set of actions performed by an individual that serves to benefit another individual or individuals, whether that action has a direct or indirect benefit to the actor.

### Introduction

Pro-social behavior, or behavior that benefits another individual, is of interest to researchers studying both humans and other animals. Perhaps because it is of widespread interest, there are a variety of different usages across disciplines. For our purposes, pro-social behavior encompasses all acts that benefit another individual, including altruism and reciprocity (the former being differentiated by a cost to the actor and the latter by the alternation of benefits between the individuals involved; see entries in this encyclopedia for more detail). Importantly, pro-social behavior does not necessarily imply pro-social *intent*; animals may act in a way that is functionally pro-social without any intention of doing so (see discussion of function versus mechanism, below). For instance, an individual may provide a benefit to another as a side effect of an action that benefits himself or herself, and there is no assumption that animals understand their actions as pro-social. Thus, it is more appropriate to discuss whether

an animal engages in pro-social behavior, which is agnostic to intent, rather than whether they behave pro-socially, which is often assumed to imply active intent on the part of the actor.

The hypothesized function of pro-social behavior is to strengthen affiliative bonds, which are critical for group-living species that must work together in at least some contexts. Pro-social behavior includes behaviors such as grooming, support, or food sharing that are widespread across species, as well as behaviors seen in a more limited number of species, such as alarm calls given to alert conspecifics to a predator's presence. Despite the hypothesized importance of pro-social behavior, it has proven remarkably difficult to demonstrate this behavior in experimental contexts. This could be because pro-social behavior is rare, of course, but this runs counter to evidence from the field, which in some species indicates fairly frequent pro-social behavior across a variety of contexts. Some authors have argued that this apparent contradiction is more likely due to subjects not understanding the purpose or mechanics of the tasks designed to elicit pro-social behavior than to pro-social behavior being rare in reality. Moreover, despite their challenges, due to the ability to manipulate factors one by one, experiments are key for understanding the contexts in which pro-social behavior occurs and determining what, if anything, subjects understand about their behavior.

Because of the breadth of potentially pro-social behaviors, for this entry we narrow to focus to a recent body of work considering the degree to which animals make decisions that benefit others. Although such decisions typically involve a small cost (the opportunity cost of making the decision), in order to maximize the chances of finding pro-social behavior, most do not entail any other costs to the actor making the choice and are therefore not altruistic. Moreover, most experiments explicitly avoid the possibility of reciprocity. Nonetheless, such work is important to consider within the contexts of both altruism and reciprocity, which we do briefly at the end of this entry. Finally, unless otherwise specified, we throughout refer to pro-social behavior in the functional sense of behavior that provides a benefit to another but remains agnostic as to the intent of the actors.

## Pro-social Behavior in Naturalistic Settings

Although recent work has focused on experimental contexts designed to understand the mechanisms underpinning pro-social behavior, original work on the topic derives from field observations or from observations made in naturalistic captive populations. Perhaps the most commonly reported pro-social behavior is grooming. Although grooming serves a biological function (i.e., removing parasites, which helps maintain health), many animals, including primates, engage in far more grooming than is necessary for health purposes and subjectively appear to enjoy being groomed. In addition, endocrine changes have been observed in conjunction with social grooming, indicating that social grooming has a physiological effect. As mentioned above, there is evidence that grooming strengthens social bonds, which can be critical for fitness. Recent work in baboons shows that females with more friends both live longer and have more surviving offspring than those with fewer friends (Silk et al. 2003). Grooming is not particularly costly nor is it zero sum (i.e., grooming one animal does not remove the possibility of grooming another, the way that food shared with one individual cannot then be shared with another), which may contribute to why it is such a widespread pro-social behavior.

Food sharing, a costlier pro-social behavior, has been seen in several primate species; however, food sharing occurs in much more limited contexts than grooming. For example, chimpanzee food sharing is generally limited to sharing with infants, excepting situations in which individuals work together to acquire food. Chimpanzees show coordinated hunting, or at least simultaneous hunting with allies, and often share the spoils of a hunt with others that participated in the hunt, even those that are not related to them (Boesch and Boesch 1989). Importantly, forest-dwelling chimpanzee populations, such as those in the Tai forest in the Ivory Coast, where tree cover is contiguous, are much more likely to meat-share than populations that live in more open grounds, such as the Gombe populations. This is presumably because the smaller, lighter monkeys they

hunt can more easily escape in contiguous forest, where they can more easily run between trees than the heavier chimpanzees, than in isolated trees, where they can be treed by individual chimpanzees. This may make coordination more essential, and meat-sharing based on hunt participation has been suggested to be a key feature in maintaining cooperative hunts. While other species engage in cooperative hunting and prey-sharing based on hunt participation (i.e., lions), this type of active meat-sharing post-hunt is more rare.

Food sharing in the form of allonursing is also seen in some species. Although uncommon, it does occur in primates; golden snub-nosed monkey and capuchin monkey females have been reported to nurse each other's offspring. Allonursing has been most often observed in species that typically reproduce in litters, such as rodent and canid species. This is hypothesized to be because a mother nursing a litter is already expending a lot of energy producing a large amount of milk, so it may be that nursing additional young incurs a low additional cost relative to the overall cost already incurred (MacLeod and Lukas 2014). However, allonursing in these primates, who produce only a single offspring at a time, is more costly. It is possible that this occurs in species in which females form very long-term relationships, changing the cost-benefit ratio, similar to what is seen with cooperative breeding.

Perhaps the most costly pro-social behavior seen in natural contexts is adoption of non-offspring, which incurs an individual cost of energy, time, and a potential loss of reproductive fitness. Both male and female wild chimpanzees have been observed adopting non-kin orphaned infants in their group upon the death of the infant's biological mother (i.e., Boesch et al. 2010). Such adoptions generally involve multiple pro-social behaviors; for example, male adopters have been observed sharing food with their adoptees, as well as providing support in aggressive conflicts with other group members, and female adopters may allonurse. Although most (but not all) cases of primate adoption occur on the death of the mother, other mammals adopt non-kin offspring following separation from their own infants (i.e., northern elephant seals). Such adoption is unlikely to be

due to a lack of recognition, because playback experiments have shown that elephant seal mothers can acoustically distinguish their pups from unknown pups, suggesting that they are actively accepting non-kin offspring.

Of course, adoption may sometimes benefit the adopters, emphasizing the fact that lines can blur between pro-social and self-beneficial behavior. Brood size in the lesser snow goose can fluctuate post-hatch and past the stage where goslings would be expected to recognize their parent, including *increasing* brood sizes, which suggests emigration of new chicks (Williams 1994). These increases in brood size appear to increase the “social rank” and viability of the group as a whole and appear to have little extra cost to the parent of the brood. Such alloparenting occurs in other birds, and aside from the social rank hypothesis, others have suggested that tolerance of added non-kin to a brood may also increase the reproductive fitness of the parent by providing their biological offspring with proximate non-kin that become potential mates.

Finally, there are numerous anecdotes about pro-social behavior, particularly in species such as primates, dolphins, elephants, and dogs. This list, not surprisingly, correlates with species that are both most often observed and are among the largest brained species; it is likely that similar behaviors observed in a species with a smaller brain would be interpreted very differently. Aside from this reporting bias, anecdotes are not typically used in animal behavior because of the risks of false positives (i.e., one pro-social-looking behavior is reported and thousands of cases in which the animals are not pro-social are not) and the risk of over-interpreting the animals’ actions, not to mention it is impossible to determine the subjects’ motivations. In many cases, purported pro-social behavior could be explained in another way, and the two interpretations cannot be disambiguated. For instance, in a famous case in which a gorilla female carried a young human child who fell into the exhibit to the keepers waiting at the enclosure’s door, there was a debate over whether her behavior represented a recognition of the young boy’s predicament and an idea for how to solve it or whether she was following

the behavior pattern she had been rewarded for previously by the keepers.

Despite these challenges, however, anecdotes can provide key insight into rarer forms of pro-social behavior. Although they cannot replace careful experiments, they can provide suggestions as to what is worth considering. For instance, there are numerous anecdotes of apes helping others who need assistance with no apparent gain on their part. This includes reports of acquiring hard-to-reach foods for older individuals or rescuing youngsters from the moat. There is some evidence of cross-species pro-social concern, such as a female bonobo who found a stunned, but otherwise unharmed, bird on the ground in her enclosure, carried it high into a tree, and, attempting to orient its wings correctly, set it loose into the air (de Waal 2009). While we can debate the weight we should put on these anecdotes, one can test them by developing experiments that replicate some aspect of the context. Indeed, given the preponderance of cooperative or pro-social interactions now documented in the literature, including across different species, anecdotes like this are useful for developing new lines of inquiry.

## Experimental Evidence of Pro-social Behavior

Despite the substantial body of field literature implying pro-social behavior, most of this fieldwork is observational, limiting our ability to determine subjects’ motivations and the underlying mechanisms. As a result, recent work has moved to the lab, where conditions can be tightly controlled. Somewhat surprisingly, however, finding evidence of pro-social behavior in experimental tests has proven to be difficult. While this could indicate that the supposedly pro-social behavior witnessed in observational contexts has other explanations, it is also possible that the subjects either failed to understand the purpose or mechanisms of the tasks (i.e., did not understand the contingencies of an apparatus), or that the experiments did not involve a context that would typically elicit pro-social responses. The majority of

the work in this area has been in primates, although it will be important to see how other species respond as well.

The most commonly used paradigm is the *pro-social choice task*. The basic task involves giving the subject a choice between an option that rewards both subject and a conspecific (the “pro-social” option) and an option that rewards only the subject. Subjects are said to behave pro-socially if they choose the pro-social option more frequently when in the presence of a conspecific – that is, when there is someone to benefit – than when alone (called the partner absent condition). This partner absent control is critical for useful interpretation of results, because without it, it is difficult to assess if subjects are making choices based on some criterion irrelevant for pro-social choice (for instance, the total amount of food that is present or a mistaken belief that they will be able to access the food). A benefit of this task is that, aside from testing pro-social behavior, it is easy to include variations that alter the benefit to the actor or the action required to benefit the recipient (effectively changing the “cost”).

This task has been used in a variety of species that have shown naturally occurring pro-social behavior, but nonetheless, results are quite mixed. The history of pro-social studies in chimpanzees nicely illustrates the challenges of designing a task for complex social behaviors. Early studies in chimpanzees, all based on the pro-social choice design, yielded no evidence of pro-social decision-making. In one early task, chimpanzee subjects were given a choice between two platforms, each of which contained a reward for the subject and one of which also contained a reward for the conspecific (if present). Rewards were obtained by pulling in a “sweeper” that brought the foods within reach. Chimpanzees were no more likely to choose the option that delivered food to both themselves and their partner when the partner was present than when they were absent, which they hypothesized meant that the chimpanzees were not choosing to be pro-social (Silk et al. 2005). Another study, completed independently but at the same time, used a slightly different design and found the same results (Jensen et al. 2006). In addition to the pro-social

option, this latter study included both an altruism condition (subjects could reward partners, but not themselves) and a spite condition (subjects could actively block partners from receiving food), yet the chimpanzees never responded in a way that indicated that they were sensitive to anything but their own outcomes. This study also included an additional control that was not possible in the first study but that suggested that the subjects understood which foods were available in the different conditions.

One hypothesis for why the chimpanzees were not pro-social was that they were so focused on their own rewards that they failed to pay any attention to their partners. This could have explained their apparent understanding of the task, yet their failure to behave pro-socially. Thus, in a subsequent design, chimpanzees were given the option to acquire their own reward followed by their partner’s. The prediction was that if the challenge for the chimpanzees was that they were too focused on their own outcomes to pay attention to their partner’s needs, this would allow them to do so. Nonetheless, subjects again failed to choose the option that helped their partner at any higher rate when their partner was present than absent (although they always obtained their own food; Vonk et al. 2008). Another hypothesis was that the chimpanzees may not have behaved differently because there was no reason to do so; after all, one key hypothesis for the evolution of helping behavior is reciprocity, and in these studies the partner was never in a position to reciprocate. To test whether reciprocity played a role, pairs received the same pro-social choice task as in Silk et al. (2005) but alternated access to the apparatus on a trial-by-trial basis. The prediction was that they would behave more pro-socially in this reciprocal condition, but yet again, they did not make pro-social choices (Brosnan et al. 2009).

Another possibility was that chimpanzees were simply not pro-social in such tasks. To address this, experimenters tested bonobos, a great ape species that is closely related to chimpanzees but is considered a more peaceful and affiliative species than chimpanzees (who are generally considered more competitive). Therefore, the

expectation might be that bonobo subjects are more likely to act pro-socially. However, bonobos were not more likely to choose pro-socially in an analogue of the pro-social choice task (Tan et al. 2015), and evidence for food sharing differences between chimpanzees and bonobos has been inconsistent. This supports the hypothesis that it may be something about the task that is challenging, and indeed, even human children have failed to exhibit pro-sociality in the no-cost primate version of the task due to the attentional demands required, so the failure of other primates to do so is not necessarily surprising.

Of course, all of the above studies shared in common a reliance on food sharing as the expression of pro-social choice, and in most cases in the wild, pro-social behavior is elicited in non-food contexts, such as providing grooming or support. Thus, experimenters also began testing pro-social behavior in a more naturalistic way using a helping task, in which the subject gives aid to another individual to help the recipient achieve some goal or reward. As many primates have been observed helping in-group conspecifics in the wild, it may also be more ecologically relevant. In a series of early tests, a small sample of young chimpanzees helped both a human experimenter and each other acquire out of reach objects, even if doing so required extra effort (Warneken and Tomasello 2006), although they failed to do the same when the experimenter's goal was less obvious (as in avoiding a physical barrier). Subsequent studies by this group indicated that chimpanzees were sensitive to whether assistance was actually needed by a conspecific. Further, in a flexible helping task, chimpanzees were able to assess what tool would best benefit a conspecific, and spontaneously provided that tool (Yamamoto et al. 2009).

Because of the success of the helping tasks, researchers again questioned why chimpanzees – who do share food in at least some contexts – were not doing so in the pro-social choice tasks. New methods focused on altering the methods of the task to be more relevant to the chimpanzees. For example, one possibility was that the barpull task was too complicated, and indeed, when subjects chose between two tokens (rather than

pulling in one of two options), they more often chose the pro-social option (Horner et al. 2011). This study was criticized for not including a partner absent condition, and this result failed to be replicated in subsequent study (Amici et al. 2014); however, a key point was that in this task, the food rewards were not visible to the subject throughout a trial. In helping tasks, too, the occlusion of the recipient food reward or using symbols to represent food quantities was more likely to produce pro-social results. These results indicated that the presence or absence of visible food could be a crucial task feature in both the pro-social and the helping tasks.

Two more recent studies strongly suggest that the chimpanzees either did not understand or were not motivated by the pro-social choice task in its original form. In the first, the researchers replicated the original Silk et al. (2005) pro-social task with the same subjects and apparatus, with one tweak; after subjects had experience as the actor making the choice, they were given experience as the *recipient* to another chimpanzee who had been trained to always make the pro-social choice. Following this, the subject was put back with their original partner and given another pro-social choice test. Initially, no subject showed evidence of pro-social behavior but, after experience as the recipient, they began to choose the pro-social option more frequently when with their partner, indicating that they may have learned something about either the goals of the task or the experience of their partner (these are not mutually exclusive; Claidiere et al. 2015). In the second study, chimpanzee subjects only got the option to make a pro-social choice after their partner (who would be the recipient of a pro-social choice) gave up food in order to unlock the apparatus. Subjects were far more pro-social subsequent to this than in control conditions in which the partner's initial unlocking was unnecessary, or a human experimenter unlocked the apparatus (Schmelz et al. 2017). Indeed, they even chose the pro-social option when the partner got more than they did, to a limit. This indicates that chimpanzees may only be motivated to provide pro-social rewards when there is a reason to do so, something that was not present in earlier studies.

Other species have showed far more evidence of pro-social behavior even with the original pro-social choice task, although there remains variability. Capuchin monkeys, a species that, like chimpanzees, are highly cooperative and has a large brain-to-body ratio (a purported measure of cognitive ability), made other-regarding choices on both a version of the pro-social choice task (Lakshminarayanan and Santos 2008) and the token-based task (de Waal et al. 2008), as well as the helping task (Drayton and Santos 2014). As in the chimpanzees, however, the response is not consistent. Capuchins in another study were only pro-social when the disparity between their reward and their conspecific's was relatively low (Brosnan et al. 2010), and the same monkeys who succeed on the token-based task showed no evidence of pro-social behavior on several alternatives, such as a touch screen version of the task or an alternate helping task in which they could provide rewards to a conspecific partner. In addition, the abovementioned replication of both the pro-social choice tasks and the token study not only found no evidence of pro-social behavior in chimpanzees, but no evidence in either capuchins or spider monkeys, either (Amici et al. 2014). It's not clear why capuchins would make pro-social decisions in more contexts than did chimpanzees, but it may relate to either their social system or a different interpretation of the experimental context.

Finally, some of the best evidence of pro-social behavior in the primates comes from callitrichids, a cooperatively breeding species of New World monkey. In cooperatively breeding species, many individuals in a group help to raise offspring within the group, and both parents provide equal amounts of investment in offspring rearing. One hypothesis in the literature is that a cooperative breeding system may encourage pro-social decision-making, due to this interdependence. Consistent with this, common marmosets given the choice to donate to an unrelated recipient are more likely to behave pro-socially to a bonded pair-mate than to an empty cage; interestingly, only male and female "breeder" individuals showed this pattern, while female "helper" marmosets were no more likely

to choose pro-socially than without a recipient present (Burkart et al. 2007). However, this pattern isn't always consistent; marmosets are *less* likely to donate altruistically to a groupmate than to a stranger, although when given oxytocin, a hormone related to bonding, marmosets now prefer to behave pro-socially toward a familiar pair-mate rather than a conspecific stranger (Mustoe et al. 2015; see discussion of the endocrinology of pro-social behavior below). This hypothesis is supported outside the primate literature as well. Although not all corvids make pro-social choices, cooperative breeding azure-winged magpies do (Horn et al. 2016).

Some of the best evidence of pro-social behavior comes from rodents. Rats will spontaneously free a trapped cagemate, even before they open container of chocolate, and often even shared the chocolate with the freed cagemate. Rats also provide evidence as to what factors influence pro-social behavior. For instance, rats help familiar cagemates and strangers of familiar strains more than conspecifics of unfamiliar strains (Bartal et al. 2014). One key distinction between the rodent tasks and the version presented to other species is that the rodent tasks all feature a salient negative stimulus, in the form of a distressed conspecific, whereas the pro-social choice task both has less emotional valence and involves providing a positive benefit rather than taking away a stressor. It may be that pro-social behavior is simply more likely in such negative, high valence contexts, although rats appear to be pro-social in more positively valenced contexts as well. In addition, the partner's distress may be an aversive stimulus, which may increase the chances of subjects acting to help (this has been ruled out in several tasks). Overall, this series of studies reiterates the importance of context and the subjects' understanding and interpretation of the paradigm in studying pro-social behavior.

## Factors Influencing Pro-social Behavior

In order to understand when and under what conditions pro-social behavior occurs, and to understand its evolution, it is important to understand

the social and contextual factors that affect pro-social behavior.

### **Dominance**

Because pro-social behavior involves an interaction between two or more individuals, it's unsurprising that these behaviors would be influenced by the social relationship. Indeed, as dominants typically obtain more resources, and lower-cost services such as grooming are typically directed up the hierarchy, a reasonable hypothesis is that dominant individuals would receive more benefits from lower-ranking individuals than the reverse. However, in a modified pro-social task, dominant rhesus macaques were more likely to deliver the food to a subordinate monkey than vice versa (Massen et al. 2010). The authors hypothesize that dominants were using generosity to maintain alliances with subordinates and preserve their status, a result supported in other primate species: dominant chimpanzees are more often involved in food transfer than more subordinate individuals. Observations of avian species, such as rooks, indicates that seemingly altruistic food sharing may be used as a costly symbol by dominants that wish to broadcast their high-ranking status.

### **Existing Social Bonds**

There is a large body of evidence suggesting that individuals act more pro-socially toward a recipient with whom they have an existing affiliative relationship. This intuitively makes sense; an existing affiliative relationship by definition indicates recurring interactions with the same individual, presumably increasing the benefit of pro-social behavior for the actor (or the cost of failing to be nice). Indeed, capuchin monkeys are more likely to choose a pro-social option when paired with a close social partner (de Waal et al. 2008), and, as discussed above, rats help members of familiar strains, but not unfamiliar ones. Similarly, female mice (but not male mice) will approach a trapped and suffering same-sex familiar conspecific to initiate social contact, and they do so significantly more than they approach an unfamiliar conspecific in the same situation (Langford et al. 2010). This isn't always the case. Black-tufted marmosets were less inclined

to share with groupmates than they were with strangers (Mustoe et al. 2015). The authors posit, however, that this is because in this cooperatively breeding species, a stranger is a potential new group member and thus may be a high priority for establishing social bonds.

### **Communicated Intent**

It has also been hypothesized that pro-social behavior should be influenced by the partner's need and that, in particular, pro-social behavior may be more common when the recipient has expressed need. There has been virtually no evidence for this in primates; however, in corvids, a recipient's approach to a reward area increased the likelihood that an actor would choose to reward both them self and the recipient rather than just themselves. However, the researchers that conducted the study posit that this effect was due to the attention directing to the reward rather than to the recipient's inherent desire for the reward (Schwab et al. 2012). Indeed, despite these being species with complex communicative repertoires, it is unclear whether the recipients even indicate desire in this way.

### **Hormonal Influences**

Differences in endogenous (i.e., naturally occurring) hormones may influence the likelihood of an actor behaving pro-socially. Perhaps the most researched is oxytocin, a neuropeptide hormone that has a variety of effects on social bonding in mammals, often in mother-infant interactions or sexual behaviors. Evidence from multiple primate species supports an association between urinary oxytocin levels and rates of affiliative behaviors and strength of social relationships among individuals (Crockford et al. 2013). Supporting the hypothesis that oxytocin plays a causal role in pro-social behavior, oxytocin treatment appeared to shift the preferences to behave pro-socially to an in-group member in marmosets, a cooperative breeding species (Mustoe et al. 2015). However, there has been very little evidence of oxytocin influencing pro-social or cooperative behavior in other studies, suggesting that while endogenous oxytocin rates may vary with pro-social behavior, there is not a causal link such that increasing

oxytocin increases pro-social behavior or, if there is, it is quite a bit more complicated. For instance, oxytocin interacts with another hormone, cortisol, to produce anxiolytic effects in humans and, it is hypothesized, other species. Such a physiological interaction might inform the emergence of social contact behaviors in response to a conspecific's pain, as observed in mice. The differing levels of these endogenous hormones and their interaction are all factors that play a key role in determining an individual's behavior in a given context, especially in species that exhibit complex social cognition, and more research in this area is clearly warranted.

### Cognitive Factors

There has been some debate about which socio-cognitive abilities are necessary for pro-social behavior to emerge. On the one hand, functional pro-social behavior may be based on positive social reinforcement of certain types of behavior, which requires little in the way of cognition. On the other hand, understanding others' needs or the effect of one's behaviors on others could lead to more complex or directed forms of pro-social behavior. Theory of mind, or the ability to attribute mental states to or take the perspective of others, would allow individuals to make inferences about another's needs or desires using those behavior cues and has been hypothesized to be integral to altruism and helping behavior. For instance, subjects could predict what a conspecific might want, which would be useful in tailoring specific pro-social behaviors (Barnes et al. 2008). However, there is not a lot of evidence for perspective taking in other species, which may indicate that it is not an essential component of pro-social behavior, however useful it might be. Indeed, many species that display pro-social behaviors both in experimental paradigms and in wild observations do not show evidence of theory of mind; even the great apes species show only limited abilities to take the perspective of others, and predicting conspecifics' future actions is complicated no matter what level of social cognition a species possesses.

Another hypothesized mechanism is empathy, the phenomenon in which one individual's

emotional or mental state is affected by the emotional state of another (de Waal 2009). While this can be quite complex, it can also be as simple as mirroring of another's emotional state, which may be sufficient to induce pro-social behavior in many species. This would allow pro-social behavior without complex social cognition; if another's distress or desire causes discomfort to an actor, that actor is likely to act in a way that alleviates that discomfort. For instance, when rats act altruistically to help a conspecific, it may be that the recipient's distress causes cognitive discomfort in the actor, who then acts to alleviate that discomfort (Bartal et al. 2014). Therefore, pro-social behavior does not seem to require such complex social cognition, but instead may use a much simpler mechanism to achieve the same end of group cohesion.

### Future Directions

Pro-social behavior is hypothesized to be important in animal social groups, but more work is needed to determine the degree to which it is seen across species and contexts, as well as the underlying mechanisms. For instance, one prominent hypothesis for the evolution of pro-social behavior is the cooperative breeding hypothesis, but to date it is based on evidence from only primates and corvids. Future work should expand to other cooperatively breeding species. In addition, an area that needs more exploration is how pro-social behavior differs toward individuals who are new immigrants to the group, or strangers versus a long-term groupmates. This is likely to vary depending on whether the new individual is seen as a threat or a potential mate and will presumably also differ depending on the residents' status in the group. In particular, it would be interesting to see how pro-social behavior changes in pair bonded species across the course of their relationship, from pair bond formation through reproduction.

Finally, more work is needed to clarify underlying mechanisms of pro-social behavior. It is not clear in which contexts perspective taking is useful, nor do we know much about the underlying

hormonal correlates. It would also be useful to determine how pro-social behavior changes depending on whether the context is to provide help, to provide a good (i.e., food), or to help an individual avoid or escape a negative reinforcer. As the current literature consists of a mix of methods, it can be challenging to compare results from different species or contexts to one another. Understanding this complexity and the subtleties of context will be critical in further exploring pro-social behavior.

## Introduction

Animals and human beings tend to recognize others by seeing their face, and this constitutes one of the cornerstones for determining the type of relationship and degree of interaction between individuals. Primates in the apex of evolutionary pyramid could even recognize the emotional expressions showed upon the face and could identify the internal milieu of the confronting counterparts and their amicability. The face, either as a complete image or in parts, gets registered in the areas of brain, and upon subsequent encounter, the reactivation of the stored image helps in recognition of the person as such. The ability to recognize and recollect the person upon seeing their face differs from one individual to other. This ability is strongly dependent upon visual expertise pathways and extent of memory representation. However, some subjects tend to fail in recognizing even the faces which are well-known to them, and such impairment is termed as “prosopagnosia.” The terminology was coined by Bodamer (1947) who had witnessed three patients with evident brain damage suffering from selective impairment in recollecting whether they have seen the face before or not. It is essential to keep in mind that not all subjects, with or without brain lesion, who could not recognize persons by face, should be labelled under this condition. Either a subject with visual impairment or a subject with generalized impairment in object recognition or a subject with diminishing memory or a subject with cognitive disturbances might harbor similar complaints (Corrow et al. 2016). But, to deem as the purest form of prosopagnosia, the subject should have difficulty in identifying the face as such and rely upon cues

such as hairstyle or voice to embark their identification process (Corrow et al. 2016; Duchaine and Nakayama 2005). They could name the parts of the face or sometimes even identify the emotions in it, but connection between a particular face and a particular identity is absent in them.

Prosopagnosia could be either developmental, where the presentation is there without any overt brain lesion, or acquired, where the presentation is the resultant of structural brain damage. Acquired brain lesion could be due to the result of different pathologies including injury, ischemic infarcts, infections, tumors, degeneration, or surgical resection of selected areas (Barton 2008). Developmental prosopagnosia usually runs in families and is more frequent compared to acquired form (Susilo and Duchaine 2013).

### Cognitive Perspectives of Prosopagnosia

To understand it better, we shall reiterate the cognitive basis behind processing of faces. Bruce and Young (1986) proposed a model for face processing which is a sequential structural encoding neural schema. When we see a person's face, the pictorial code gets generated in an abstract form, and upon seeing the same or different photograph of the corresponding person, matching takes place leading to identification. Familiarity gained out of repeated exposure leads to generation of face recognition units which can activate personal identity-specific semantic codes (Eimer and McCarthy 1999). Thus, the code generation pattern differs depending upon familiarity, and unfamiliar faces are predominantly recognized by their distinct physical properties which culminate in generalized identity such as race and country. Stronger personal identity nodes lead to unified access to other semantic information regarding the individual such as their profession, past experiences, recalling names, etc. According to Damasio et al. (1982), prosopagnosia is the clinical resultant of one of the three mechanisms: (a) destruction of templates archived in the

cortical areas, (b) inaccessibility of the templates, and (c) inactivation of the templates after access. Even normal individuals tend to misrecognize faces, and this happens when there is lack of inactivation of templates. But prosopagnosia should only be considered when there is a failure in transference and matching of the pictorial code with the identity-specific semantic codes upon stimulus. In other words, it is the result of damage to a cognitive system specific to visual processing of facial identity.

Yet another hypothesis proposed is "configural processing hypothesis" which states that subjects with prosopagnosia could not get the overview of the face at a single glance, and this results in the failure of recognition (Levine and Calvanio 1989). This hypothesis is supported by the fact that these patients could match and compare several features of the face in a sequential manner as in face matching tests. However, this hypothesis is not supported by strong evidence because face identification cannot be considered as a set of discernible objects and the visual processing stream required for objects is different from the one required for face identification (Moscovitch et al. 1997). McNeil and Warrington (1993) observed that subject with prosopagnosia had difficulty in recognizing human face, and this ability to recognize sheep was unimpaired. Farah (1996) postulated the concept of two-shape representation systems, whereby one construct is broken down into numerous sub-components. Face recognition systems are holistic when compared to other recognition systems such as words which are handled by part-based system and objects which are handled by combination of both. When part-based systems become defective, it results in alexia and damage to holistic system results in prosopagnosia. The clinical spectrum of presentations result even when there is slight decomposition of shape, and this could be attributed to the different degree of malfunctioning of processing systems. This could also be explained based on the difference in visual processing streams, and thus a comprehensive knowledge regarding the cortical areas involved in face recognition is essential.

## Cortical Areas Involved in Face Recognition

Neurons involved in facial recognition are distributed as clusters in the superior temporal sulcus of humans and also in nonhuman primates such as macaque monkeys (Moeller et al. 2008; Tsao and Livingstone 2008). Functional neuroimaging studies have showed that some areas of the brain are highly involved in recognizing the face when compared to other objects (Haxby et al. 2002; Kanwisher and Barton 2011). Three principal areas responsible for synchronized processing the face are inferior occipital gyrus, middle lateral fusiform gyrus, and posterior part of superior temporal sulcus (Kanwisher and Barton 2011). Electrical stimulation of occipital face area made the subjects to temporarily lack their ability to recognize the faces of celebrities (Jonas et al. 2012), and when the same stimulus was given in fusiform face area, perceptions of facial structures got distorted when compared to control objects (Rangarajan et al. 2014). Rossion et al. (2003) documented that the loss of right inferior lateral occipital lobe and left medial temporal lobe (where fusiform gyrus is located) would present with prosopagnosia.

Studies (Wachsmuth et al. 1994; Logothetis et al. 1999) have shown that humans have a category-specific and segregated modular organization related to different stimuli. Similarly, in macaque monkeys, neurons which respond maximally to face images are predominantly located around superior temporal sulcus and inferior temporal cortex (Allison et al. 1999; Chao et al. 1999). These neurons are usually clustered either as patches or columns (Allison et al. 1999). Another study based on neurophysiological recordings in the macaque visual cortex observed that anterior temporal area acts as the storehouse of image-invariant representations of facial identity irrespective of rotations (Meyers et al. 2015). When compared with non-face objects, cells in the superior temporal sulcus show 20-fold increased selectivity for face selection (Pinsk et al. 2005). Especially, the posterior most region of the temporal lobe, located 6 mm anterior to the interaural canal, was the most

selective region. In macaque monkeys, there exists functional specialization such that along the occipitotemporal direction, face selectivity increases (Bell et al. 2009). Similarly, confusion of mirror symmetry emerges, and facial identity increases in strength (Axelrod and Yovel 2012).

The extent of activation of face area differs according to the dominance of the cerebral hemisphere, and in majority of human and non-human primates, right hemisphere is superior compared to left counterpart (Tsao et al. 2003). The chances of developing prosopagnosia are more when the dominant hemisphere gets damaged. Another interesting mechanism which has been proposed for developmental prosopagnosia is the defect in the subcortical mechanisms. De Gelder and Stekelenburg (de Gelder et al. 1999) proposed that infants tend to attend to faces because of their subcortical mechanism and, if it is defective, they would neither attend to the faces nor process it for further storage. In cases with congenital prosopagnosia, it has been found that the volume of anterior fusiform gyrus is reduced (Behrmann et al. 2005). Diffuse tensor imaging and tractography also showed impaired structural connectivity in the ventral occipitotemporal cortex (Behrmann et al. 2005). Thus, compromise in the core region of ventral occipitotemporal cortex and its peripheral processing units in anterior temporal and frontal cortices would be the plausible hypothesis for congenital prosopagnosia. Recent works have used unique functional signature to facial processing, namely, N170 which is a form of event-related potential for understanding the mechanism of prosopagnosia (Bentin et al. 1996). The results of these works showed that developmental prosopagnosia is highly heterogeneous and presentation can be from subtler to severe forms.

Leaving behind the acquired causes which overtly lead to the disruption in connectivity and result in clinical presentation, the etiology for developmental and congenital prosopagnosia might be either due to transmissible mutations of the gene or significant events during infancy. Another model which has been proposed is the neurodevelopmental disorder due to the defective migration of neurons which ultimately result in

compromised cognitive abilities (Ramus 2004). Applying the hypothesis, neural migration errors in the fusiform gyrus and superior temporal sulcus could be the plausible hypothesis for developmental prosopagnosia which is a highly circumscribed dysplasia (Duchaine et al. 2006). With respect to therapeutics, even though many regimens have been tried including oxytocin which has given feeble benefits in increasing the social interactivity in developmental prosopagnosia patients, none could yield significant proof of benefits (Bate et al. 2014).

## Conclusion

Prosopagnosia is characterized by heterogeneity of clinical presentations which differs across developmental and acquired forms. The extent and nature of structural damage is the significant determinant for clinical outcome. Even though laboratory findings and neuroimaging studies have shown the processing stream related to face recognition and genetic factors with significant clarity, there are still questions regarding the interaction of face recognition processing streams with other object recognition streams. This can be attributed to the small patient sample in which the disease has been studied along with inconsistency in experimental models. Further studies involving large patient sample, accurate definition criteria, and advanced imaging tests would yield better knowledge regarding prosopagnosia.

Prospective memory (PM) is defined as the ability to complete a planned action at a specified time in the future (Einstein and McDaniel 1990). There are many situations in which an individual needs to do something, but cannot accomplish the goal at the present moment, so the intention must be retained and remembered at an appropriate time. For instance, a student may think about needing to call her mother while taking an exam, but cannot do so until the test is complete and the student is out of the classroom. But will she remember to do so? Is she more likely to forget if distracting events occur right after the test? The study of these processes and the potentially influencing factors is the focus of PM research. In a traditional PM task – which has been primarily conducted with human adults in laboratory settings – the participant is engaged in an ongoing task with the stipulation that when a particular event occurs (i.e., the PM target), the participant should make a unique response to that event which is distinct from their response to the ongoing task. A common variant of this paradigm is to have participants complete a lexical decision task with the PM instructions to press a particular key when a target word (e.g., *history*) appears on the screen. This is thought to mimic the key dual-task components of how PM might occur in non-laboratory

settings (e.g., remembering to stop and mail a package on the drive home from work).

Researchers have broadly classified PM tasks into two varieties. Event-based PM refers to situations in which the intended action should be performed when a particular external event is encountered. Time-based PM refers to scenarios where an individual must remember to perform the action after a particular amount of time has elapsed (e.g., 15 min) or at a particular time (e.g., 3:00 PM). At a general level, time-based tasks are typically associated with worse performance than event-based tasks (e.g., Sellen et al. 1997). No matter the task, theorists have noted that successful PM retrieval relies on several sub-processes including, intention formation or planning, retention of the planned intention over a delay interval, recognition of cues that signal the appropriate time to perform the action, and the ability to remember and execute the planned action (Ellis 1996). Importantly, in PM tasks, there are no explicit retrieval cues that signal to the individual to initiate the retrieval, as is the case with retrospective memory tasks.

Prospective memory research expands our understanding of memory in general. Further, research suggests that PM accuracy is sensitive to a variety of factors, including the characteristics of the remembering environment. For example, highly salient cues (McDaniel and Einstein 2000), instructions that stress the importance of PM success (Walter and Meier 2014), and situations in which noticing of the PM target happens naturally as a part of completing the ongoing task (i.e., focality; Einstein et al. 2005) have all been shown to promote highly accurate remembering. In the case of focal tasks, these high levels of PM are obtained while incurring no costs to the ongoing task, suggesting to some researchers that retrieval of PM intentions in certain situations is spontaneous or automatic (McDaniel and Einstein 2000; Scullin et al. 2010). In contrast, when noticing of the PM target does not overlap with the ongoing task (i.e., nonfocal tasks), PM performance has been shown to rely on controlled attentional monitoring processes dedicated to noticing and responding to the target events (e.g., Smith 2003).

Another important reason for research into PM in humans is that increased PM failures are associated with cognitive decline in normal aging (Crystal 2013). Recent meta-analyses on the effects of aging demonstrated PM impairments in laboratory tasks for older adults relative to younger adults, and these effects were present even when retrieval was thought to be mediated by spontaneous processes (Henry et al. 2004; Kliegel et al. 2008). These age-related effects of declining PM ability can be devastating, such as forgetting to take critical medication at the appropriate time, and efforts are underway to develop interventions or treatments to aid PM performance. The establishment of a validated animal model of PM opens up opportunities to study these interventions in a controlled manner. Of course, one important question in this pursuit is the extent to which PM abilities are exhibited in nonhumans. One can imagine many scenarios in which PM would be advantageous for a number of animal species. For example, some species must remember the location of a particular fruiting-tree and, critical to PM, they also must remember to move to this foraging location at the appropriate future time in order to reap its benefits. Animals have also shown evidence of future-oriented cognition (e.g., Bräuer and Call 2015), which overlaps with PM ability. The study of these processes offers insight into the nature of PM and may also allow for carefully controlled studies on interventions or PM training if animal models can be validated.

Early work suggested that animals might exhibit prospective coding or prospective memory like behaviors as well as retrospective memory (e.g., Cook et al. 1985; Murray and Gaffan 2006; Rainer et al. 1999). More recent work has continued to support this possibility and expanded the species under investigation. Jon Crystal and colleagues have provided a compelling line of support for PM in rats. Initially, rats were trained to classify a tone as either short or long, also known as a temporal bisection task. After performing this task for a certain period of time, rats were given free access to a food source. They found that the rats would engage in anticipatory behaviors (e.g., begin poking their noses into the

food trough), which required a break from the bisection task, as the time to the end of the session grew near (Wilson and Crystal 2012). These findings align with the time-based prospective memory tasks used in humans and suggest continuity across species. In addition to the time-based PM work, these researchers have created an event-based PM paradigm for rats. The rats learned that a tone would signal when extra food would be freely available. At the sound of the tone, performance on the ongoing task declined (Wilson et al. 2013). These findings suggested that rats may respond similarly to an event cuing that a different response may now be appropriate.

In addition to the work with rodents, there has been an increasing focus on investigating non-human primate PM. Primates offer a model which affords many similarities and overlaps with the features of human PM and further suggests evolutionary continuity in the ability. Evans and Beran (2012) trained capuchin and rhesus monkeys on a computerized task designed to test PM ability. On some test sessions of an ongoing computer game, a visual stimulus would signal that an additional reward could be earned by making a particular response at the end of that block of trials (but not immediately). Monkeys successfully performed both aspects of the task (the ongoing task and the PM task), and they even initiated the response (i.e., began moving the cursor with the joystick) in the PM blocks before the stimuli were visible on the screen, suggesting that subjects were anticipating the opportunity to make this special response.

In another study addressing the possibility of PM in chimpanzees, a single language-trained chimpanzee was given the choice between two food items (Beran et al. 2012). The chosen item was immediately scattered around an adjacent outdoor yard and the unselected item remained in a container indoors. The subject was given access to the outdoor yard and allowed to forage for food for 30 min. In addition to the scattered food, there also were lexigram tokens (images representing various food types) in the same space. One of these tokens matched the identity of the item that remained inside. If the subject chose to, she could find the correct token and

bring it back inside to exchange for the food hidden in the container. This reflected many critical parts of PM tasks because the subject had to form an intention that could not be fulfilled immediately. If, at the appropriate time (i.e., once the preferred item had been consumed), the subject could successfully fulfill the intention (i.e., remember and find the correct token to trade indoors), then the PM intention could be executed and the additional food items would be given to the subject. The subject returned the correct token successfully on the majority of test trials and significantly more often than on control trials in which no additional food was hidden indoors.

Finally, a more general task was designed to test PM using a similar methodology in children and chimpanzees (Perdue et al. 2014). Human and nonhuman subjects were again given a choice between two items (food for chimpanzees, toys for children). The unchosen item was hidden in a container. Subjects then had to complete an ongoing quantity judgment task. At the end of that task, a request to the hidden container (via pointing or gesturing from the chimpanzees or asking from the children) would allow the subject to obtain the contents of the container. The chimpanzees and the children – sometimes given additional prompts – performed fairly well on the task, suggesting that they were retaining the intention to retrieve the hidden item even during the ongoing task.

All of the animal tasks described thus far vary somewhat from the human literature in that the new response should occur at the end of an ongoing task (Beran et al. 2015). This is a subtle but potentially important distinction from the human work in which the participants must self-initiate disengagement from the ongoing task at an appropriate time. One recent study attempted to test this ability in chimpanzees with a task that required active disengagement from an ongoing task to complete the PM intention (Evans et al. 2014). The chimpanzees were trained to sort tokens representing various food types into one of two trays. On some trials, an actual food item that would later be shown on the picture cards was placed in a hidden container in the back of the enclosure at the beginning of the test session. The

chimpanzee could retrieve that item if it traded the matching token out when it was later presented. The subject was shown the contents of the container at the beginning of the trial, but the experimenter engaged in the sorting task did not know if food was hidden or not, nor did they know the identity of the food. When the token for the hidden food was given to the chimpanzee later in the test session, the chimpanzee could either sort it into one of the piles for a small food reward, or, if the chimpanzee remembered the intention to get that real food item, he or she could disengage from the sorting task and use the token to retrieve the hidden item. Thus, the chimpanzees had to successfully recall the information in addition to remembering to act at the appropriate time. The pattern of performance on this task closely matches human performance on a PM task. Subjects had to retain an intention that could not be acted on immediately, and disengage from an ongoing task at an appropriate time to fulfill the intention.

All of the comparative research suggests substantial overlap between human and nonhuman animal prospective memory and great potential for future work in this domain (Crystal and Wilson 2015).

## Protandrous Hermaphroditism

Jonathan M. Henshaw

Department of Biological Sciences, University of Idaho, Moscow, ID, USA

Division of Ecology and Evolution, Research School of Biology, The Australian National University, Canberra, ACT, Australia

## Synonyms

Protandric hermaphroditism; Protandry

## Definition

A reproductive system where individuals mature as males, but may reproduce as females later in life.

## Introduction

In most animals, “males” and “females” are distinct classes of individuals that specialize in the production of sperm and eggs, respectively. However, a substantial minority of species are hermaphrodites, meaning that a single individual can produce both eggs and sperm, either simultaneously or at different stages of its life. “Protandrous” hermaphrodites begin their reproductive lives as males, but reproduce as females later in life.

Two examples help to illustrate (Fig. 1). Anemonefish live in small territorial groups, where reproduction and sex change are determined by a strict dominance hierarchy (Munday et al. 2006). The largest individual in the group is a breeding female, the second-largest is a breeding male, and all smaller individuals are non-breeding males. If the female dies or is removed, then the largest male changes sex and takes her place. Protandrous hermaphroditism is also found in several species of “cleaner” shrimp that feed on the parasites and dead tissue of their fish clients. In shrimps of the genus *Lyssmata*, individuals begin their reproductive lives as males, but can reproduce as both sexes later in life (Bauer 2006).

## Terminology

Protandrous hermaphroditism encompasses a continuum of life histories, distinguished by the degree of temporal overlap between male and female reproduction (Collin 2013; Fig. 2):

1. *Protandrous sequential hermaphroditism*: Reproduce early as a pure male, and later as a pure female.
2. *Protandrous hermaphroditism with overlap*: Reproduce early as a pure male, and later as a pure female, with an intervening period of reproduction as both sexes.
3. *Protandrous simultaneous hermaphroditism*: Reproduce early as a pure male, and later as both sexes.

**Protandrous Hermaphroditism, Fig. 1** (a) An adult and juveniles of the Oman anemonefish *Amphiprion omanensis*, a protandrous sequential hermaphrodite, shown with the host anemone *Entacmaea quadricolor* (Photo taken from Simpson et al. **Protandrous Hermaphroditism, Fig. 2** Schematic showing different forms of protandrous hermaphroditism, distinguished by the degree of temporal overlap between male function (green lines) and female function (purple lines) over an individual's lifetime (cf. Collin 2013)

Still further along this continuum are species that reproduce as both sexes over their whole reproductive lifespans (i.e., life-long simultaneous hermaphrodites), but shift their relative allocation of resources from male to female reproduction over time (Leonard 2013). There are also species that start out as simultaneous hermaphrodites, but later reproduce as pure females. Neither of these latter life histories is commonly referred to as “protandrous.”

Sex change is usually unidirectional. In a few taxa, however, the gonad degenerates between reproductive seasons, and sex is redetermined at the start of the next season (Collin 2013). Protandry may then occur within each reproductive

season. A very small number of species exhibit flexible bidirectional sex change (Munday et al. 2006). These species are sometimes called “protandrous” if the initial sex is invariably male.

These definitions emphasize reproduction (i.e., functional sex) rather than morphological criteria, because the adaptive significance of protandry is best understood by looking at reproductive success via each sex (Policansky 1982). The distinction matters because an individual may reproduce consistently as one sex (i.e., produce only one gamete type) and yet contain reproductive tissues typical of the other sex (Sadovy de Mitcheson and Liu 2008). Particular care should be taken in comparisons with the botanical literature, where

“protandry” is often defined according to purely morphological criteria (Policansky 1982). In defining *when* an organism acts as a male or female, the timing of fertilization is the most useable criterion. For instance, in some species sperm mature earlier than eggs, even though both types of gamete are used in the same reproductive episode; these species should be classified as simultaneous hermaphrodites rather than sequential (Policansky 1982). This convention can lead to curious consequences when there is a long delay between the production and fertilization of gametes (e.g., due to storage of received sperm). For instance, a protandrous individual may act as a male (i.e., achieve fertilization) long after it ceases producing sperm.

## Diagnosis and Detection

Protandrous hermaphroditism should ideally be diagnosed using (1) histological series of the gonads or other gametogenic tissues showing the stages of transition (e.g., from functioning testis to functioning ovary for protandrous sequential hermaphrodites), and/or (2) field or laboratory observations of sex change in individual animals, based on unambiguous behaviors such as spawning (Sadovy de Mitcheson and Liu 2008). External sex characteristics and behaviors are not always reliable indicators of functional sex. Even when assessing the gonads, care must be taken to distinguish functional tissues from immature, vestigial, or otherwise nonfunctional tissues that do not produce mature gametes (Sadovy de Mitcheson and Liu 2008).

Differences in age or size distributions between males and females (or simultaneous hermaphrodites) can be suggestive of protandry, but should not be relied on as the only line of evidence. This is because (1) these patterns can equally be caused by sex differences in maturation or mortality, and (2) protandrous species may in any case show substantial overlap between the sexes, which may not be detected in low-powered studies (Charnov 1982; Sadovy de Mitcheson and Liu 2008).

These relatively stringent diagnostic requirements probably lead to under-detection of protandrous hermaphroditism (Policansky 1982; Collin 2013). In practice, separate sexes are usually assumed if no simultaneously hermaphroditic individuals are found; simultaneous hermaphroditism may similarly be diagnosed based on a small sample of individuals with both gonad types. Some species that are currently classified as separate-sexed may consequently be protandrous sequential hermaphrodites, whereas some supposedly simultaneous hermaphrodites may have an undiscovered protandrous phase (Leonard 2013).

## Occurrence

Protandrous hermaphroditism is rare but taxonomically widespread, occurring in a diverse range of animal phyla (Policansky 1982). In vertebrates, protandrous sequential hermaphroditism is known in the clownfish (subfamily Amphiprionina of the Pomacentridae), porgies (Sparidae), and flatheads (Platycephalidae), with isolated examples in several other fish families (Sadovy de Mitcheson and Liu 2008). All three forms of protandry are well-represented in the mollusks, including both gastropods (e.g., true limpets, Patellogastropoda; slipper limpets, Calyptraeidae) and bivalves (e.g., oysters, Ostidae; scallops, Pectinidae) (Collin 2013). Protandrous hermaphroditism is rare in crustaceans, but occurs in many decapod shrimp (Charnov 1982; Bauer 2006). Protandry is notably very rare in freshwater fish and entirely absent in land vertebrates and insects. Most protandrous species have close relatives that are separate-sexed or simultaneous hermaphrodites, indicating that protandry has evolved many times independently (Charnov 1982; Collin 2013).

## Mechanisms and Cues of Sex Change

Protandrous sex change is underpinned by a wide variety of mechanisms, consistent with its taxonomic diversity. Some taxa have clearly separated

ovaries and testes, whereas others combine ovarian and testicular tissue inside a single organ, called an ovotestis (Policansky 1982). Germ cells may specialize as one sex early in development or remain sexually bipotent for extended periods (Sadovy de Mitcheson and Liu 2008). In teleost fish, the endocrinal cues of sex change are highly species-specific, most likely reflecting the multiple independent origins of protandry, although gonadal steroids appear to play a key role in all studied species (Frisch 2004).

In protandrous sequential hermaphrodites, sex change is almost always sensitive to social cues such as the sex and size of nearby individuals (Munday et al. 2006; Leonard 2013). For instance, the largest individual in a pair or group may be female, while smaller individuals are male. Even when sex change is more gradual, it may respond to environmental or social indicators of the potential for reproduction via each sex (Charnov 1982; Leonard 2013).

## Evolution and Adaptive Significance

To explain the evolution of protandrous hermaphroditism, theorists have explored how the

potential for reproductive success changes with size (or sometimes age) for each sex. Two kinds of size effects are commonly studied: (1) “budget” effects, in which the benefits of size are due simply to greater resource availability, and (2) “direct” effects, which are benefits of size per se (e.g., the dominance hierarchies of anemonefish) (Leonard 2013).

For protandrous simultaneous hermaphroditism, the most prevalent explanations rely on budget effects. For instance, suppose reproductive success is primarily determined by investment into gametes. If there is limited competition among the sperm of different individuals, then sperm production may bring diminishing fitness returns with increasing investment, while egg production shows more linear returns (Charnov 1982; see Fig. 3). Smaller individuals, with fewer resources at their disposal, should then invest only in sperm production, to make use of the higher initial returns. Larger individuals should invest more heavily in egg production, while continuing to produce a small amount of sperm (Fig. 3).

For protandrous sequential hermaphroditism, the most influential explanation is the size advantage model, which is based on direct effects of size

**Protandrous Hermaphroditism, Fig. 3** (a) Hypothetical relationship between gamete investment and the rate of fitness gain for male function (green) and female function (purple). For female function, fitness increases linearly with investment, whereas for male function, fitness increases steeply at first but then levels off. (b) The optimal investment of resources into male and female reproduction, shown as the total resources available to an individual varies, assuming the fitness gain curves from panel (a). If

the individual has a small resource budget, it is optimal to invest only in male function. As the resource level increases, the marginal gains from female function eventually equal those from male function (marked as a black dot with dotted tangent line). After this point, all additional resources should be invested in female function. If access to resources increases with age, this selects for protandrous simultaneous hermaphroditism

on reproduction. It predicts that when reproductive success increases more rapidly with size in females than males, that individuals should begin their lives as females and then change sex (Warner 1975; Charnov 1982; see Fig. 4). Faster growth or lower mortality in males than females may similarly select for protandrous sequential hermaphroditism (Kazancıoğlu and Alonzo 2009). The model implicitly assumes that it is optimal to reproduce as only one sex at a time (i.e., no simultaneous hermaphroditism).

The size advantage model has been successful in predicting the direction and even the timing of sex change (e.g., Charnov 1982), but less effective at predicting its taxonomic distribution. Indeed, given the near-ubiquity of sex differences in growth, mortality and size-specific fecundity, many authors have questioned why sequential hermaphroditism is not more common (Warner 1975; Charnov 1982; Kazancıoğlu and Alonzo 2009; Leonard 2013). Sex change may be selected against if there are large costs associated with changing sex (e.g., due to the need to restructure the reproductive organs or secondary sexual traits: Kazancıoğlu and Alonzo 2009). Evolutionary transitions from separate sexes to protandry may also face developmental or morphological

constraints associated with combining two previously separate sex functions in a single individual (Charnov 1982). Even considering these factors, our ability to explain the distribution of protandrous hermaphroditism in any of its forms remains very limited (Leonard 2013).

Definition

Protein is a biomolecule consist of carbon, hydrogen, oxygen, nitrogen, and a small amount of sulfur with a chain of amino acids forming a complex folded and functional structure. Protein performs several crucial functions in the living entity, such as maintenance and growth of body, transcription factor, chemical messenger, immunogenic substance, energy provider.

Introduction

Protein is considered as one of the major important biomolecules included in our daily diet because of its nutritional and caloric value. The

term protein, derived from the Greek word “Proteois,” means primary. The term protein was coined by Swedish chemist Jacob Berzelius in 1839. The structural and functional unit of protein is an amino acid that was unknown even after its discovery in 1830. The 20 standard amino acids are either nutritionally essential or not depending on its synthesis in our body (McCoy et al. 1935). They are coded either in single letter or in three digits which is easy and more comprehensive in sequencing and Bioinformatics (Lehninger et al. 2000; Voet et al. 2008) (Table 1).

Protein, Table 1 List of amino acids in alphabetical order

| 1-digit code | Amino acid     | Code (3-digit) | Nutritionally essential |
|--------------|----------------|----------------|-------------------------|

## Protein Evolution

The genetic information of an individual stored in DNA transcribes into mRNA and thereafter translates into amino acids which polymerize and folded to form functional protein. Over long periods of time, protein randomly mutate and the survive individuals with mutated form brings the evolutionary change in the process of natural selection. The protein sequences are conserved mostly among species due to divergent evolution or common ancestry. The amino acids sequences in proteins among the inter- and intra-species are present in a conserved manner. These evolutionarily conserved sequences in the proteins are named as domains which can be grouped into different families. Domains with >40% similarities have a similar function and <25% similarities differ in their function. Nonidentical protein performing the same function in different species is considered as homologue. Homologous proteins with similar function in different species are named as orthologues (e.g., Cyt C or hemoglobin in different species), whereas in a similar species due to gene duplication the same protein varies in their sequences and roles are called paralogues (e.g., Hemoglobin and myoglobin in globin family in same species). Amino acid sequences comparison of homologous protein in different species helps to draw the phylogenetic tree. Different proteins have different evolutionary rates except histone proteins which are highly conserved in evolutionary history.

## Structural Organization of Protein

Proteins are unbranched polymers constructed from 20 standard  $\alpha$ -amino acids. They have four levels of structural organization. Genetic information specifies the amino acid sequences of the primary structure. As the polypeptide chain folds, it forms certain localized arrangements of adjacent amino acids that constitute the secondary structure. The overall three-dimensional shape that a polypeptide assumes is called tertiary structure. Proteins that consist of two or more polypeptide chains are said to have a quaternary structure.

## Protein Metabolism

Protein is the final product of a gene. Genes are present in the specific loci of DNA in the chromosome. mRNA is synthesized from DNA by the process of transcription in the nucleus which undergoes translation in the cytoplasm to form proteins. Co-transcription-translation occurs in prokaryotes. Three nucleotide sequence presents in mRNA (codon) specifies the amino acid. Specific t-RNA with the corresponding anticodon sequence bears the specific amino acid and helps in the formation of a polypeptide by reading the mRNA sequence.

## Amino Acid Synthesis

The capacity to synthesize amino acid differs for protein synthesis in living organisms. Plants and many microorganisms can synthesize all 20 standard amino acids from readily available precursors (such as glutamate and glutamine from  $\alpha$ -keto glutarate, serine, glycine and cysteine from 3-phosphoglycerate, alanine, valine, and leucine from pyruvate; These are all intermediates of glycolysis or Krebs cycle).

**Some of the important functions of proteins**  
(<https://www.healthline.com/nutrition/functions-of-protein>)

- (i) General growth and maintenance of tissues in body
- (ii) Participate in biochemical reactions
- (iii) Acting as a messenger
- (iv) Structural backbone
- (v) pH maintenance
- (vi) Fluid balance
- (vii) Provide immunity
- (viii) Transport and storage of nutrients
- (ix) Energy provider (4.1 Kcal)

## Ailment Due to Protein Misfolding or Deregulation in Metabolism and Energy Malnutrition

The following table (Table 2) is the list of diseases due to misfolding, deregulation, and energy malnutrition of protein.

**Protein, Table 2** List of diseases

| Disease type                 | Diseases                                        | Cause                                                                                | Comment                                                           |
|------------------------------|-------------------------------------------------|--------------------------------------------------------------------------------------|-------------------------------------------------------------------|
| Protein metabolism disorders | Gout                                            | Uric acid overproduction and deposition in synovial fluid                            | Excessive intake of red meat                                      |
|                              | PKU (phenyl ketonuria)                          | Defect in enzyme (phenyl alanine hydroxylase) for phenylalanine/tyrosine degradation | Accumulation of phenyl alanine                                    |
|                              | Alkaptonuria                                    | Absence of homogentisate oxidase, failure of homogentisic acid breakdown             | Dark black urine                                                  |
|                              | Albinism                                        | Tyrosinase enzyme deficiency                                                         | Lack of synthesis of melanin pigment                              |
|                              | Tyrosinemia                                     | Tyrosine transaminase loss                                                           | Tyrosine degradation hampered                                     |
|                              | Cystinuria                                      | Increased excretion of cystine                                                       | Cystine stone in kidney                                           |
|                              | Homocystinuria                                  | Homocystine accumulation                                                             |                                                                   |
|                              | Cystinosis                                      | Cysteine crystals deposition in tissues and organs                                   | Lysosomal dysfunction                                             |
|                              | Glycinuria                                      | Excess glycine excreted in urine                                                     |                                                                   |

## Conclusion

Proteins are one of the major and most important nutritional biomolecules. They consist of a polymer of amino acids, which helps in the maintenance of bone, muscle, and the entire framework of the body, acts as an enzyme, hormone, transcription factors and when not properly folded or

functionally anomalous causes severe ailments in the body.

## Proteome

Daniel B. Stamos

National Institutes of Health, National Institute of Child Health and Human Development, Bethesda, MD, USA

## Definition

The set of proteins encoded by the genome. This includes the added changes that are made to proteins by a posttranslational modification (PTM) (Adams 2008). The proteome is dynamic and is constantly changing depending on the needs of a cell. Proteomics refers to the study of the proteome.

## Introduction: What Is the Proteome and Why Study It

To better understand how cells function and where cells get their defining characteristics from, scientists have taken a keen interest in elucidating the composition of proteins within an organism. This has spurred the field of proteomics.

The proteome is the set of proteins that is encoded by an organism's genome. In the broadest sense, the proteome could refer to all the proteins that are encoded by an organism's genome. However, the various cellular subsets

within an organism have different functions and subsequently have different protein compositions. Despite having the same genome, these different cellular subsets will have different protein makeups. Therefore, one can study the proteome of an organ such as the liver, a tissue type such as vasculature, or a lineage of cells such as hematopoietic cells. In fact, one could even go as small as an individual cell's proteome.

Biologists have known for decades that the human genome encodes the information needed to create all the proteins of an organism. Through scrupulous genomic control mechanisms, the proteins that are required for each cell to function are meticulously expressed and regulated. It is the unique genetic expression profile of each cell – and the proteins that stem from this expression pattern – that gives a cell its identity and ultimately its function.

## The Proteome: A Dynamic System

When studying the proteome, it is important to remember that the proteins that a cell requires, and produces, are constantly changing (Adams 2008). When a cell responds to a signal from a neighboring cell or conditions in the extracellular environment, there will be an accompanying change in the intracellular protein composition (Adams 2008). Cell cycle stage, cellular needs, genomic regulation, developmental stage, and much more will also affect the expression level of proteins in a cell (Larance and Lamond 2015). These changes in protein concentration ensure that a cell is best suited to fulfill its function and thrive in its environment.

Thus, the unique complement of proteins contained by each cell in an organism, and the constant flux of protein concentration that occurs in response to the ever-changing cellular milieu, makes the proteome a transmutable entity. The dynamic nature of the proteome is in direct contrast with an organism's genome, whose sequence of nucleotides is the same in every cell of an organism (Adams 2008).

## Posttranslational Modifications as an Important Source of Dynamism and Diversity

Certain biochemical processes play vital roles in the dynamism of the proteome. One such process is PTMs. There are over 200 types of PTMs (Brett et al. 2002), which allows for a vast array of protein modifications. These PTMs add even more complexity to a protein and allows one gene to generate unique protein products in different cells. A PTM is a change made to a protein after it has been translated from RNA. After a protein has been synthesized, sugars, lipids, phosphates, and even other proteins can be added to alter a protein (Adams 2008). In some cases, a protein may not be functional until a PTM has been made. The location of these modifications on a protein also affects the protein's structure and function. Sometimes a protein is cleaved to regulate its activity, either activating or inactivating it (Jensen 2006). A PTM does not need to occur to every protein of a given type to have an effect. For example, 5% of a protein population being phosphorylated may be enough to activate a signaling pathway in a cell even though the other 95% of the protein population is unmodified and inactive (Jensen 2006). PTMs help make the proteome a complex, changing network. PTMs are tightly regulated, which enables a cell to have access to the specific protein it needs to function. Depending on the requirements of a cell at a given time, a PTM will or will not be made.

## Alternative Splicing and Its Role in the Proteome

Another contributing source of dynamism in the proteome is alternative splicing. When RNA is transcribed in the nucleus, it is made from coding exons and noncoding introns. The final mRNA product is made by splicing exons together to make a unique mRNA transcript. Alternative splicing is the cell's ability to make multiple splice variants at the RNA level. Some of these RNA variants can encode distinct protein isoforms (Kim et al. 2014). Because one gene has many

coding exons, the way alternative splicing arranges these exons will produce unique mRNA transcripts (Kim et al. 2014). Even though these mRNA transcripts arise from the same gene, their unique exon arrangement will allow them to be made into different proteins.

Intron retention is another type of alternative splicing, but intron retention is used to down-regulate the expression of a protein (Liu et al. 2017). In intron retention, at least one intron is spliced into the mRNA transcript. When this occurs, the mRNA transcript's ability to exit the nucleus is altered since mRNA transcripts with introns may not be competent to exit the nucleus (Liu et al. 2017). Intron retention may also insert a premature stop codon into the mRNA transcript causing protein degradation by the nonsense-mediated decay pathway (Liu et al. 2017). Recent studies show that around a third of genes can make unique protein isoforms from alternative splicing (Kim et al. 2014). Again, through stringent regulation, alternative splicing allows an organism to alter its protein composition in real time to satisfy its immediate biological needs.

## Conclusions

As researchers further attempt to understand cell biology, interest in proteomics will only intensify. The proteome itself is a wide-ranging term, which could refer to the study of an entire organism's, or a single cell's, protein composition. When studying the proteome, it is important to remember that it is a dynamic system. An organism's proteome will vary from day to day and even hour to hour as an organism responds to the specific stimuli it is presented with.

PTMs and alternative splicing are important sources of dynamism and diversity in a cell's proteome. A common theme in the proteome is the tight regulation of the processes that make it dynamic and diverse. It is a cell's precise control over the expression of its genome that gives each cell its unique function, and allows a cell to rapidly change its intracellular protein makeup.

With technologies such as mass spectrometry improving every day, researchers will be able to

glean even more information from the proteome. This will continue to give scientists invaluable insights into biology and will bring us closer to understanding the fundamental biochemistry of life.

## Proto-counting

Michael J. Beran

Department of Psychology and Language  
Research Center, Georgia State University,  
Atlanta, GA, USA

Studies of the quantitative and numerical abilities of nonhuman animals extend back to the earliest days of comparative psychology. A variety of terms have been applied to the different kinds of abilities that animals show when given tests that require them to quantify stimuli. This encyclopedia contains many of these terms, and the present article introduces one of the more controversial terms – proto-counting. This term was championed most successfully in the highly influential *Behavioral and Brain Sciences* paper by Davis and Perusse (1988). In that article, they made a distinction between true counting behavior and performances that lack the essential features of true counting but also cannot be ascribed to processes such as subitizing, relative numerosness judgments, or absolute numerosness judgments. In essence, proto-counting has come to refer to instances of counting-like behavior of animals where not all of the defining principles are met, perhaps because of methodological constraints or perhaps because some principles were not assessed.

To illustrate this idea, one must first understand the widely accepted criteria for true counting

behavior. These criteria were first offered by Gelman and Gallistel (1978) and basically consist of five principles:

1. The one-to-one principle states that during a counting event each item in a to-be-counted set should be given a unique tag so that there is an exact correspondence between all items and their unique tags. In other words, an individual who is counting must tag each thing once and only once.
2. The stable-order principle underlies the idea of ordinality, and it basically says that the tags that are used are always applied in the same order. For example, “3” is always the third tag applied, always comes after “2” and is always followed by “4.”
3. The cardinality principle says that the final tag is special: it represents not only the tag of the individually last tallied item, but also of the sum total of the counted set. Thus, last tags represent totals, and when presented with that tag, it represents a specific number as well as a specific ordinal position within a counting sequence.
4. The order irrelevance principle says that the tagging of stimuli can occur in any order, as long as that tagging satisfies the one-to-one principle, and the resulting cardinal value will still be accurate. In other words, counting pennies from left to right, right to left, or in terms of shininess will still produce the same cardinal knowledge.
5. The abstraction principle says that the above three principles can be applied to any set of stimuli to generate ordinal and cardinal knowledge, including highly abstract things such as jumps, remembered birthdays, and other such things. Those principles also can be applied to highly varied stimuli, such as counting the number of electronic devices in a home, or the number of species in a zoo.

These principles have guided some of the research into the numerical abilities of non-human animals. Various tasks to assess counting-like behavior have been designed and used with species ranging from insects to great

apes and those tasks are too numerous to describe or document in this article. The key issue for this article is the idea that in nearly all of those cases, the term proto-counting would be applied as defined above because of limitations in what those studies could show. For example, a chimpanzee named Sheba learned to label sets of items with an Arabic numeral, including in cases where multiple subsets had to be combined. She also showed evidence of tagging those items with touches to them, and so there was evidence of one-to-one correspondence, ordinality, and cardinality, but there was no indication that she could be given a numeral and collect items equivalent in number to that symbol (see Boysen 1993). Other chimpanzees used Arabic numerals to guide their responses of collecting sets of items on a computer screen equal in number to that numeral value, but they were never asked to do a labeling task (e.g., Beran and Rumbaugh 2001). So, full evidence of the counting principles was not present in those cases. In another impressive project, the parrot Alex was able to label sets according to their numerosity and announce subsets of a specific quantity, and Alex also showed the ability to do this with all kinds of stimulus types, including heterogeneous sets of things (see Pepperberg 2006). However, it was not clear that Alex engaged in tagging of items in any way, allowing again the claim that this would be proto-counting.

What is compelling is the breadth of proto-counting in the animal kingdom. Although primates, parrots, and other large-brained animals have shown strong evidence of proto-counting, so too have other more diverse species. For example, rats have been shown to enumerate the number of tunnel runs they encountered to find a specific cardinal value that predicted food reward (e.g., food is in the fourth tunnel; Capaldi and Miller 1988). Similar designs have shown that honeybees can enumerate specific numbers of tunnels or landmarks to pass by to find the correct site that predicts reward (e.g., Chittka and Geiger 1995; Dacke and Srinivasan 2008) and ants perform various foraging tasks that also rely on numerical cues and some of the counting

principles (e.g., Reznikova and Ryabko 2011). Pigeons also show cardinality and ordinality in their use of symbols representing labels for enumerated sets and also as cues to how many items need to be collected (e.g., Xia et al. 2000, 2001), but this was in only one testing context. Thus, in many of these cases, proto-counting would be the claimed mechanism solely because of lack of transfer tests of the ability to apply counting routines to completely new types of stimuli. Of course, this is a high bar given that transfer tests given to human children are scaffolded by language, and clear verbal instructions can be given in new contexts, whereas this cannot be done with animals. So, it is very difficult to show such transfer for methodological reasons. In other cases, real behavioral limitations are evident in nicely designed transfer tests, or tests where numerical symbols must be used flexibly for ordinal and cardinal relations. For example, honeybees can learn associations between quantities and arbitrary signs, but not in a bi-directional manner necessary for counting. This means that honeybees that learned to match a sign to a number of elements were not able to use that sign to indicate which numerosity to choose as a match (Howard et al. 2019).

Ultimately, most researchers working in this area today concern themselves less with the question of whether these behaviors are *counting* or *proto-counting* and instead the focus is on the degree to which numerosity is the defining stimulus feature of the representation that drives responding. Although there are still claims of counting by animals, no cases present as comparable to what the average 5-year-old human child can do fairly easily. But, that should not be the goal of this comparative research, to confirm that counting is “real” or that some new experiment definitely moves an animal’s performance from proto-counting to “true” counting. Our goal in this comparative research is to understand what numbers mean to animals, how they can (or cannot) enumerate different types of stimuli, and how accurately they can represent quantitative information in symbolic form. Ultimately, what one calls

these performances is less valuable than how well one understands them.

## Protogynous Hermaphroditism

Brett M. Taylor

Joint Institute for Marine and Atmospheric Research, University of Hawaii, Honolulu, HI, USA

Fisheries Research and Monitoring Division, NOAA Pacific Islands Fisheries Science Center, Honolulu, HI, USA

The sexual ontogeny and developmental patterns of organisms are incredibly diverse. Much of this diversity is rooted in interspecific variability in sex allocation, which is the provision of resources to either female or male reproduction in order to optimize reproductive success for individuals and populations. *Protogynous hermaphroditism* refers to a life-history characteristic, whereby individuals in a population change sex from functional females to functional males at some point during their life span. Hence, resource investment is more heavily allocated to female reproduction early in the life span, and later this investment switches to male reproduction. Hermaphroditism has been documented in a range of taxa, including both terrestrial and marine invertebrates and vertebrates, but is highly common and very well studied in many families of teleost fishes, particularly coral reef fishes with complex social systems, as is evidenced by the high volume of scientific literature examining protogyny in coral reef fishes. Because younger individuals are generally female and older individuals are generally male, protogynous populations are often sexually dimorphic (i.e., males, on average, are larger than females) and in some cases sexually dichromatic (i.e., sex change is concomitant with a change in body coloration or other morphological characteristics).

Protogyny is a form of sequential hermaphroditism, which is a trait where individuals function as both sexes at different times in their life spans, necessitating a transition from one sex to the other. The theory behind sex allocation (Charnov 1982)

provides a framework for understanding the advantages of variable distribution of resources among males and females in a population. The central tenet regarding the evolutionary cause of sequential hermaphroditism is the “size-advantage hypothesis” (Ghiselin 1969), which predicts that sequential hermaphroditism will be favored when reproductive fitness increases with size (and therefore age) at a greater rate in one sex than the other. Hence, for protogynous species, optimal resource allocation would be exhibited by a predominance of females at smaller body sizes and a switch to males at larger body sizes (Warner 1975). Protogynous hermaphroditism is common in species with complex mating systems. Mating strategies, such as harem territoriality where large males defend territories and harems of smaller females, influence the fertility rates of both males and females across different body sizes. This suggests that the optimal timing of sex change for individuals is strongly determined by the extant social system, such that an individual will change sex if and when it increases their reproductive value (Munday et al. 2006a).

Protogynous hermaphrodites can display either monandry or diandry. Monandric species are those in which all males in the population are derived secondarily from functional females, termed secondary males. Diandric species have two pathways of male development and, thus, two types of males. Primary males become functional males at the onset of maturation; secondary males are derived only through sex change from functional females. In sexually dichromatic (i.e., different colorations broadly associated with females and males) species, primary males often display initial phase coloration, which is generally associated with females, but some of these individuals will later undergo metamorphosis to terminal phase coloration. This change is generally concomitant with a behavioral change in reproductive strategy. The sexual patterns described here are common in the well-studied Labridae (wrasses and parrotfishes), but the nuances of sexual ontogeny can be much more complex and variable across other taxa.

Factors controlling the onset of sex change or the development as a primary male in individuals

have been clearly linked to social organization and mating system (Ross 1990). Warner and Swearer (1991), using the oft-studied bluehead wrasse (*Thalassoma bifasciatum*), demonstrated one-to-one replacement of terminal phase males that were removed from local populations. Replacement occurred via sex change in the largest remaining initial phase females. Munday et al. (2006b), using the same model species, showed that development of primary males was determined by the resident population size, whereby primary males are more prevalent within larger resident populations. These strategies relate to reproductive success rates of different sexes and phenotypes under different mating systems, which vary with local population size. In fact, among the teleost fishes, the evolutionary history of functional hermaphroditism appears highly associated with the structure of mating systems (Erisman et al. 2013).

Previously, the wide range of studies examining factors controlling sex change were conducted at very small spatial scales, often in controlled experimental settings. However, because social systems, population size, and resource availability can vary across space and time, there is tremendous spatial and temporal variability in life-history strategies within species. Warner (1991) proposed utilizing the vast levels of intraspecific variability across space and time to test hypotheses in evolutionary ecology. He states, "[...] phenotypic plasticity of a trait within a species represents a set of functional adaptive responses to short-term variation in the environment. A study of phenotypic plasticity can identify just which aspects of the environment appear important in eliciting a functional response. [...] Given a particular trait, the environmental factors to which a particular species responds in the short term should be the same as those that shape differences between species over evolutionary time." The length at sex change in protogynous hermaphrodites is among the more labile life-history traits, and, in some dichromatic species, can be accurately and rapidly estimated by relating lengths of individuals with body color phases. Expanding observations up to scales stretching

across diverse ecosystems or across species ranges represents a new frontier in studying protogynous hermaphroditism and should facilitate a greater understanding of the extent of local adaptation in populations (Petersen and Warner 2002).

## Protolanguage

G. Thomas Frost  
Quincy University, Quincy, IL, USA

### Definition

The term “protolanguage” occurs in the linguistics literature with two different meanings. One meaning of the term refers to a language (in general extinct) from which a family of modern languages is descended. An example is Latin, which gave rise to the Romance family of languages. Whereas Latin is an attested language (known to us through preserved documents), in other cases the progenitor language is unattested, known only by reconstruction from the attested languages that descend from it. An example is the hypothetical language of Proto-Indo-European, from which all modern Indo-European languages have developed.

The other meaning of the term, which will be emphasized here, is a hypothetical stage in the biological evolution of language in the hominin lineage. According to the theory of language origins proposed by linguist Derek Bickerton (1990, 1995), hominins in the protolanguage stage (which Bickerton associates with *Homo erectus*) communicated with words that were not organized by syntactic rules. At a later point in evolution, genetic mutation gave rise to an innate “language bioprogram” (which some, although not Bickerton, would describe as a “module”) that enabled syntactically organized language to emerge (Bickerton 1984, 1990). Protolanguage, on this view, was a stepping stone toward true language.

Bickerton’s notion of protolanguage actually has broader scope than suggested above, however, as it can be observed in certain populations in the world today. These populations include children younger than 2 years, feral and closet children (those raised in social isolation and hence deprived of early exposure to language), and apes that have been taught language-like

communication systems (such as rudimentary sign language). But the modern-day form of protolanguage that plays the most central role in Bickerton’s theory of language origins is the crude system of communication known as a pidgin language.

### Introduction

During the era of European colonialism, from the sixteenth to nineteenth century, laborers from various language communities (e.g., Chinese, Koreans, Japanese, Africans, and Filipinos) were brought together in places like Haiti, Jamaica, Belize, Surinam, Mauritius, and Hawaii, in many cases, to work on sugar plantations (Bickerton 1990). Since the workers possessed no common language in this polyglot situation, there existed a need for a lingua franca to make communication possible. Uniform adoption of the superstrate language (that spoken by the master class) was inhibited, however, by the minimal opportunities for interaction between the workers and their masters in the rigidly stratified social structure. Instead, the potpourri of words known as a pidgin language emerged as the workers cobbled together lexical items originating in the superstrate language, with additional borrowings from the various substrate languages (the native languages of the workers).

A pidgin language in its early stages is a bare-bones form of communication that lacks several major features of natural languages like English or Japanese. First, function words are rare or non-existent. These are words, such as articles, conjunctions, and prepositions, that lack inherent meaning and instead play a grammatical role. They are to be contrasted with the inherently meaningful content words, which include nouns, verbs, adjectives, and adverbs, and which refer to objects, actions, and properties. A typical utterance in a pidgin language (and other forms of protolanguage) will consist almost entirely of such items. Also lacking are grammatical items such as auxiliary verbs, as well as noun and verb inflections, which mark number and tense.

A second feature that is lacking in early-stage pidgin languages is the use of word order to express differences in meaning. A simple example from English is the contrast in meaning between *John kissed Mary* versus *Mary kissed John*; these contain the same words, but due to the difference in word order, the roles of agent and patient are reversed. Pidgin languages do not sequence words in a principled manner; instead word order is highly inconsistent, with different speakers of the language tending to order words in a manner that carries over from their native language. Nor are differences in word order used to convey differences in meaning.

Framing the issue in terms of word order is a bit simplistic, however, for it seems to suggest that language consists of words strung together like beads on a string. While such a linear pattern may adequately characterize pidgin and other forms of protolanguage, the organization of true language is hierarchical rather than linear. That is because natural languages like English provide rules by which words can be built up into phrases, which can in turn be built up into still-larger phrases. For example, a noun like *dog* can be expanded into a larger noun phrase by adjoining it to the adjective *black*, resulting in *black dog*. Applying this rule recursively, we can add another adjective, yielding a still-larger noun phrase like *big black dog*. English and many other languages permit still further expansion by adjoining a specifier like *the* to a noun phrase, which in the present case would result in *the big black dog*.

Similar possibilities for expansion are also available to verbs. Thus, a transitive verb like *chase* requires an obligatory object such as *cats*, which can be combined to form a verb phrase like *chase cats*. The noun *cats* might in turn be expanded into *the small gray cats*, resulting in the larger verb phrase *chased the small gray cats*. This hierarchically structured verb phrase can now be adjoined to a subject noun phrase, itself hierarchically structured, adding yet another level to the hierarchy, resulting in a sentence like *the big black dog chased the small gray cats*. The resulting conglomerate can be diagrammed as an inverted treelike structure, where each phrase is hierarchically embedded in the next-larger

phrase, the complete assembly hanging from an overarching *S* (sentence) node.

At least, this is the case in natural languages like English. Pidgins and other forms of protolanguage lack rules for the assembly of words into more expansive phrases, resulting in a linear, rather than hierarchical, structure. This in turn limits the expressiveness of protolanguage, for example making it difficult to ascertain which of two nouns in a word string is the agent and which is the patient. We can gain deeper insight into this shortcoming of protolanguage by taking a closer look at the grammar of verbs.

As noted above, the verb *chase* requires an obligatory object such as *cats*. Other verbs sharing this property include *hit* and *kiss*. Thus, you cannot say *John hit* or *Mary kissed*, as the grammar of English requires you to state who received the hit or the kiss (as in *Mary kissed John*).

Linguists call the thing affected by an action the *patient* (typically expressed as the object of the verb), whereas the actor that performed the action plays the role of *agent* (usually expressed as the subject of the verb). These “thematic roles” and the nouns that express them are said to be *arguments* of the verb, meaning that they are role-players or participants in the action named by the verb. In contrast to transitive verbs like *chase* or *kiss*, an intransitive verb like *sleep* or *arrive* takes only a single argument (ordinarily expressed in English as the subject of the verb). Such a verb cannot take an object, and indeed it sounds strange if you try to give it one. Thus, we can say *Mary slept* but not *Mary slept the dog*. Still other verbs, such as *give*, *lend*, *send*, and *hand*, take three arguments, as in *Mary sent John a letter*.

These particularities of a given verb are said to comprise the verb’s *argument structure*. Typically, in natural languages like English, the arguments of a verb must occur obligatorily and in canonical position in the sentence structure. Thus, if Mary kissed John, we can say *Mary gave John a kiss*, but we cannot say *Mary gave a kiss John*.

The requirement for obligatory verb arguments may seem to be violated, however, by an utterance such as *What did Mary give John?* Here the supposedly obligatory object of the verb (let’s suppose it was a kiss that Mary gave to John),

which would canonically occur after *John* (as in *Mary gave John a kiss*), seems to be missing. In the transformational grammar of Chomsky (1957), this is explained as the result of so-called movement rules. If we suppose that the sentence starts out as *Mary gave John what?*, a movement rule would relocate the question word *what* to the beginning of the sentence, while also inserting a form of the auxiliary verb *do*, resulting in *What did Mary give John?*

While these phenomena are pervasive in the natural languages of the world, they are absent in protolanguage. For example, in a pidgin language, the arguments of a verb are not obligatory but rather can be omitted freely. This means that word strings like *John hit* or *Mary kiss* would be permissible. True, in natural languages a constituent may be missing from its canonical position, but when this happens, the empty slot is linked in a principled manner to an antecedent that is related to it. If we use *e* to represent such an empty slot, then in a question like *What did Mary give John e?*, the *e* is related to the question word *what*, helping us to understand that this word refers to the object of the verb *give*. As Bickerton notes, such grammatical devices permit us to interpret the language we hear in an automatic and effortless way, making it easy for us to understand who did what to whom. Protolanguage, lacking such devices, fails to provide such clarity.

It is the lack of these features in pidgin languages that relegate them to the status of protolanguage (along with the language of children before their second birthday and language-trained apes, of which more below). Bickerton sees these features of protolanguage as relevant to the evolutionary origins of language in the hominin lineage.

### Protolanguage and Bickerton's Theory of Language Origins

The relevance of protolanguage to the problem of language origins lies in the changes that occur in a pidgin language as it is passed from the first generation of pidgin speakers to their children.

In the span of one generation, a pidgin language is transformed into a much more expressive form of language called a creole. A creole language possesses all of the features that are lacking in pidgin languages (and other forms of protolanguage), including function words and hierarchical organization that is governed by phrase-formation rules.

But how does this transformation from pidgin into creole occur? Starting with function words, these do not emerge *ex nihilo* but rather consist of content words from the pidgin language that are called into service for a new purpose (Calvin and Bickerton 2000). For example, in the creole that emerged in Hawaii (known as Hawaiian Creole English), auxiliary verbs are derived from content words like *go* and *stay* (which, when used as content words, have roughly the same meanings as in English). When used as auxiliary verbs, *go* is used to mark the main verb for irrealis modality (subsuming future tense and conditional and subjunctive moods), *stay* to mark nonpunctual aspect (roughly equivalent to English progressive), and *bin* to mark anterior tense (roughly equivalent to English pluperfect) (Bickerton 1981, 1983a).

As noted above, a creole language emerges not among the first-generation immigrants but rather among their children. We know this because the adult pidgin speakers, unlike their children, seldom achieve proficiency in the creole. Rather, they continue to speak pidgin (while retaining fluency in the native language of their home country). Bickerton draws the conclusion that it is the children who created the creole language. (For alternative views on the origin of creoles, see the commentary on Bickerton's 1984 target paper.)

But why is this act of language creation possible for the children and not for their parents? Bickerton's answer is that the parental generation cannot achieve proficiency in the creole (let alone *create* such a language) because they have matured beyond the critical period for language acquisition (perhaps better described as a "sensitive" period). Their children, however, achieve full fluency in the language that they themselves have created, presumably in the course of their verbal interactions with each other.

It appears, then, that there is a discontinuity, or quantum leap, in the sophistication of language from one generation to the next. According to Bickerton a similar discontinuity occurred in the evolutionary history of language in the hominin lineage. On this view, the pidgin-to-creole transition constitutes a recapitulation of the evolutionary history of language in the hominin lineage. In the latter case, however, it was genetic mutation that accounted for the transition from protolanguage to true language, by giving rise to an innate language bioprogram containing the fundamental principles that underpin all human languages.

These are the essentials of Bickerton's (1984) language bioprogram hypothesis. Readers familiar with the linguistics literature will note the clear similarity of this theory to Noam Chomsky's (1975) theory of an innate "language organ," or "language acquisition device", embodying the principles of universal grammar (as elucidated in popular form by Pinker 1994). This notion was proposed by Chomsky to account, among other things, for how the complexities of natural languages like English, Japanese, or Swahili can be acquired in a relatively effortless manner by children. Going beyond that, Bickerton's theory proposes to explain not only how children can learn a language but can actually *create* one *de novo* when they are deprived of an even remotely adequate model, as in the pidgin situation.

Going still further, Bickerton's hypothesis provides a coherent account of certain universals that occur in the structure of all creole languages. An example is the placement of auxiliary verbs in relation to the main verb of a clause. Creole languages that have sprung up independently of each other invariably place auxiliaries before the main verb and in a uniform sequence (Bickerton 1983a, 1990). In every creole language, the anterior marker (when present in a particular utterance) precedes the irreal marker (when present), which precedes the nonpunctual marker (when present), which in turn precedes the main verb. This uniformity, on Bickerton's (1983b) account, can be seen as the default setting of innately specified parameters of the sort postulated by Chomsky's (1981) theory of principles

and parameters. (For an accessible account of Chomsky's parametric theory, see Baker 2001).

## The Diverse Forms of Protolanguage

As noted above, pidgin is not the only form that protolanguage can take but rather, according to Bickerton, is a part of the human biological endowment for language that manifests itself in additional ways, including the language of children under 2 years old. The earliest language outputs of children consist of single words, which first appear at around the age of 1 year. Children first start putting words together at around the age of 20 months. While utterance length at this stage is at most two words, children learning English evince regularities of word order that reflect the canonical SVO (subject-verb-object) pattern of this language. For example, while a three-word utterance like *Mommy throw ball* is beyond a 2-year-old's reach, two-word fragments respecting English word order such as *Mommy throw* (SV), *throw ball* (VO), or *Mommy ball* (SO) are likely to occur.

As noted by Bickerton (1990), these word-order patterns in early child language are not universal but rather reflect the syntactic pattern of the language the child is learning. For example, a child learning Japanese will produce two-word utterances reflecting the OV pattern of that language (contrasting with English VO), whereas children learning Tagalog will produce outputs conforming to the VS pattern of that language (contrasting with English SV).

While these regularities suggest that an incipient syntax is starting to emerge, this appearance is illusory according to Bickerton (1990). Even in the cases where the two-word combinations are novel (as opposed to memorized idiom-like units), the appearance of syntactic organization is superficial only. While the child may grasp the fact that nouns are different from verbs and order them in a language-appropriate way, this understanding is based on semantic rather than syntactic criteria. Thus, for a child at this age, what makes a word a noun is that it denotes a concrete object (*bed*, *toy*, *mommy*), and what makes a word a verb is that it

denotes a physical action (*run, play, eat*). Syntactically organized language will not emerge until the child recognizes that word classes are based on formal rather than semantic criteria. The language learner will then be able to talk about such things as *lack* and *absence*, which play the grammatical role of nouns but do not refer to anything concrete or perceptible to the senses.

According to Bickerton, this breakthrough occurs when the child's language module comes on-line at around the age of two, marking the transition from protolanguage to true language. While this presumably results from biologically programmed maturation, the normal development of the module requires at least minimal language input from the child's environment (although, as we have seen, even the highly impoverished input afforded by a pidgin language is sufficient). If such input is not available during the child's sensitive period, then normal language development cannot occur. We know this from the case of children who have been deprived of exposure to language during their early years.

Probably the best-known case of this is the "closet child" known as Genie, who was rescued from extreme social isolation at the age of 13. Her language at the time of her rescue was virtually nonexistent. Over the course of several months, she began to utter, at first, single words and then, later, two-word combinations (Fromkin et al. 1974). Examples include the following:

*Want milk.*  
*Paint picture.*  
*Mike paint.*

Like a normally developing child, she eventually came to produce longer utterances:

*Applesauce buy store.*  
*Father take piece wood. Hurt. Cry.*

While the second example may look like English SVO word order, according to Bickerton this ordering is based on functional rather than grammatical factors. In particular, in Genie's speech the topic of an utterance (what the utterance is "about") would always come first, meaning that it is not serving the formal role of grammatical subject, which in turn means that

we can relegate such structuring to the level of protolanguage rather than true language.

Another example suggestive of grammatical sophistication is Genie's apparent use of the grammatical device of subordination, as in the following:

*I want Curtiss play piano.*

Here we appear to have the subordinate clause *Curtiss play piano* embedded in a matrix clause that begins with *I want* – a seemingly clear example of hierarchical embedding of the sort that cannot exist in protolanguage. Bickerton discounts this, however, on the grounds that every putative example of grammatical subordination in Genie's speech began with *I want* followed by what would ordinarily be a complete utterance in itself. More to the point, there is no use of complementizers like *that* or *to*, which would mark the beginning of a subordinate clause in English (as in *I want Curtiss to play [the] piano*). What we have here, then, is better understood as the juxtaposition of clauses rather than the grammatical embedding of one clause within another (Bickerton 1990).

Although Genie made progress in her language development, and in fact this development paralleled in many ways the language development of normally developing children, this progress came to a halt when she reached roughly the level of a normal 2-year-old. This is the point where, according to Bickerton, protolanguage gives way to true language in the language development of normally developing children. This is the limit for closet children, like Genie, who cannot avail themselves of their language module, which has gone off-line by the time of their first exposure to language, bringing to a close the sensitive period for language acquisition, leaving the child stuck at the protolanguage stage.

While exposure to at least a crude form of language is necessary for normal language development to occur, it is not in itself sufficient. According to Bickerton and other language nativists, it also requires that the language learner be equipped with an innate language module. As this adaptation is unique to humans, it follows that syntactically organized language should not

be accessible to any nonhuman species. There remains the possibility, however, that with appropriate tutelage, a nonhuman might be capable of acquiring protolanguage. That such is the case has been demonstrated, in Bickerton's view, by the efforts to teach apes a form of language. Indeed, while apes have been proven capable of acquiring a lexicon of a hundred "words" or more (be they manual signs, plastic chips, or lexigrams on a computer console), according to Bickerton (1990) their quasi-linguistic outputs fail to evince a command of syntactic organization.

Such a command might seem to be demonstrated by certain regularities that appear in language-trained apes' ordering of "words" (e.g., hints of SV word order, as in *Roger tickle* or *you drink*). Moreover, in their language comprehension (as opposed to production), there is even some recognition that meaning changes when word order changes (e.g., *Roger tickle Washoe* versus *Washoe tickle Roger*). But as we saw in the case of child language acquisition, mere regularity of word order does not suffice to demonstrate a command of syntax. A more compelling indicator would be evidence of hierarchical structure, and this, according to Bickerton, is lacking in the quasi-language of apes (see also Anderson 2004). For instance, there is no embedding of one clause within another. Indeed, in this respect apes fall short of even the meager accomplishments of Genie, who at least produced a semblance of embedding in the case of outputs like *I want Curtiss play piano*.

Equally telling is the lack of function words in apes' quasi-linguistic outputs. This might be attributed to the fact that such words, unlike content words, cannot be defined ostensively, making them difficult to learn (Bickerton 1990). But this difficulty does not stop human children from learning them, where this, arguably, is made possible by a language module that exists in humans but not in apes. With regard to the comprehension (as opposed to production) of function words, apes fare no better. For example, even the high-performing bonobo Kanzi cannot distinguish between putting something on, in, or next to another thing (Anderson 2004).

The evidence reviewed to this point seems consistent with the suggestion that a non-syntactic form of language, called protolanguage, characterizes the linguistic (or quasi-linguistic) outputs of children younger than 2, closet children, and apes. The question remains, however, whether this form of communication is discontinuous from true language or whether the former can grade gradually into the latter.

## Evaluating the Theory of Protolanguage

A key feature of Bickerton's argument is that protolanguage and true language are distinct modes of behavior, each of which is an inherent part of humanity's biological endowment (and in the case of protolanguage is within the reach of apes). A corollary of this assumption is that when, in the course of ontogeny or phylogeny, protolanguage is replaced by true language, the transition is not smooth or gradual but rather involves a discontinuity. In the case of child language acquisition, the transition can be explained by the maturation of a language module that comes on-line at around the age of 2. In the biological evolution of human language, the transition was caused by a genetic mutation that gave rise to the language module in the first place. This notion of a discontinuity in language development has been questioned in at least two different ways.

First, even if such a discontinuity occurs in child language development, it does not follow that a comparable discontinuity occurred in the biological evolution of language. The reason, as noted by Pinker (1992), is that a genetic capability for forms of language intermediate between protolanguage and true language might once have existed in the hominin lineage but were selected out in the course of evolution. (Jackendoff 1999, has in fact outlined a plausible sequence of stages by which grammatical language might have evolved. And Bickerton himself in later works allowed for the incremental elaboration of the language faculty after its initial appearance in evolution (Calvin and Bickerton 2000). Consideration of these refinements in

Bickerton's theory would take us too far afield, however.)

A second and possibly more serious objection to Bickerton's notion of protolanguage as discontinuous from true language is that stages intermediate between the two can, and evidently do, exist in child language development. The existence of these stages suggests that syntax develops incrementally and not in one fell swoop. One way to see this is by examining the child's acquisition of verb argument structure. This is evidently accomplished in a piecemeal manner, one verb at a time. A verb like *cut*, for example, may initially appear only in a simple construction with one argument, for example, *cut*\_\_\_ (as in *cut paper* or *cut finger*). More-complex constructions with more than one argument, such as *daddy cut paper*, do not occur with this verb. But at the same point in development, other verbs may occur in frames that accommodate multiple slots for multiple arguments, resulting in constructions like *draw*\_\_\_ *on*\_\_\_, *draw*\_\_\_ *for*\_\_\_, \_\_\_*draw on*\_\_\_ (Tomasello 2003, 2011).

Thus, it seems that a given child's growing command of argument structure is verb-specific (for which reason these are called item-based constructions). And even within a given verb, the various constructions do not appear all at once. Rather, change occurs in a stepwise manner, with the child successively adding additional arguments to a particular verb (Tomasello 2003, 2011). It seems, therefore, that rather than acquiring abstract rules that apply generally to all verbs, the child initially learns the various constructions possible for each verb one at a time, and these are based on how the child has heard that particular verb being used (Tomasello 2003, 2011). This poses a challenge to the "words-and-rules" approach to language development of the sort advocated by Pinker (1999), where this process is seen as depending on a Chomsky-type language module. If that were the case, and if this module comes on-line at around the age of 2 years, as Bickerton suggests, then one might expect, contrary to fact, that the child would acquire a particular argument structure, applying across the board to many verbs, all at once. The fact that this kind of sweeping

change does not occur seems more consistent with operation of general-purpose learning mechanisms than with the sudden awakening of a dedicated rule-learning mechanism.

Indeed, the very notion of an innate language module, or language "instinct," has been called into question (Tomasello 1995). Instead, general-purpose learning and cognitive mechanisms may be adequate to account for language acquisition (Tomasello 2003). And if a language module does not exist, this undercuts the rationale for positing two distinct kinds of language, one of which (true language) depends on such a module, while the other (protolanguage) does not.

## Synonyms

[Cocaktiel locomotion](#); [Cockatoo locomotion](#);  
[Parrot locomotion](#)

## Definition

Movement used by members of order Psittaciformes to traverse their environment. The order is subdivided into 3 superfamilies—Psittacoidea, or true parrots, Strigopoidea, or New Zealand parrots, and Cacacuoidea, or cockatoos and cockatiels (Luescher 2006).

Parrots, cockatoos, and cockatiels are skillful foragers within tropical and sub-tropical rainforests, in part due to their unique limb morphology. Their zygodactyl feet, in which the first and fourth digits face backward while the second and third digits face forward, assist in both perching and climbing. The tarsus, which lies between the heel and toes, is characteristically short and stout, allowing parrots to climb and manipulate objects easily (Parr and Juniper 2010; Toft and Wright 2015). Sedentary parrots invest a significant amount of time and energy into building strong, well-protected nests to incubate eggs and raise their young. Due to their migrant lifestyle, nomadic parrots opt for large clutches and spend less time incubating and rearing their young (Luescher 2006).

## Flight Biomechanics

There is debate within the field of avian flight biomechanics on classifying gait during flight, since birds mostly stray from typical terrestrial locomotion. Historically, studies have utilized two-dimensional models to understand flight aerodynamics and to classify gait. Others have proposed that instead of discrete gait classification, kinematics should be quantified through a Strouhal number (wingbeat frequency \* wingbeat amplitude/forward flight speed). Tobalske (2007) explains that all birds seek to maintain their Strouhal number through flight by accordingly modifying aerodynamic variables. Recent technological advancements, including high speed cameras and turbulence-simulating wind tunnels, have allowed for a three-dimensional study of avian locomotion. These studies have revealed that gait patterns largely overlap between members of the same order. Psittaciformes primarily rely on flapping flight as a main gait pattern, as opposed to gliding, soaring, hovering, or short-flight. In addition to flapping flight, each family within the order has adapted unique characteristics to their gait, to optimize energy cost based on body composition (Deetjen et al. 2017; Hedrick et al. 2002; Nespolo et al. 2018).

Cockatiels (*Nymphicus hollandicus*) of the superfamily, Cacatuoidea, will be used as the archetype for discussing general flight patterns of Psittaciformes. At slow speed flight (<7 m/sec), cockatiels primarily use downstrokes, or downward directed flapping, resulting in a vortex-ring gait (Fig. 1). At slower flight speeds, cockatiels use downstrokes to forcefully push air downward. This

maneuver helps to either maintain the bird's flight altitude or assist in climbing to higher altitudes, known as lift. Forceful downstrokes cause the air trailing behind each distal wingtip to swirl and form a vortex at each wingtip. At slow speeds, these vortices connect in the cockatiel's wake, forming a single vortex ring. During the slow-speed upstroke, cockatiels and other Psittaciformes utilize a "tip reversal upstroke" or "upstroke flick," whereby their wings remain extended, but their feathers are supinated to allow air flow. However, the upstroke provides little to no vortex shedding or lift. This mechanism is characteristic of parrots, but the true aerodynamic purpose remains unknown (Hedrick et al. 2002).

At 7 m/sec, cockatiels transition from vortex-ring gait to continuous vortex gait by accelerating upward and forward. This transition occurs through several high-amplitude wingbeats followed by several low-amplitude wingbeats. Vortex-ring gait and ladder-wake gait are used for brief periods of acceleration, while continuous vortex gait is used for brief periods of deceleration during gait transition. Ladder-wake gaits occurs when downstroke air circulation is greater than the upstroke (Hedrick et al. 2002; Pennycuik 1988).

At high speed flight (>7 m/sec), cockatiels use both upstrokes and downstrokes, resulting in two separate trailing vortices—one from each wingtip, known as continuous vortex gait. The vortices are formed via equivalent air circulation from the proximal wingtip during the upstroke and the distal wingtip during the downstroke. The continuous upstroke–downstroke cycle produces lift with forward velocity, providing most of the air

**Psittaciformes Locomotion, Fig. 1** During flight Psittaciformes transition between different “gaits,” such as (a) vortex-ring gait, (b) ladder-wake gait, and (c) continuous vortex gait. (Figure adapted from Hedrick et al. (2002))

flow. The “upstroke flick” is not commonly used at high speed flight. At maximum speed flight (~15 m/sec), cockatiels utilize ladder-wake gait to minimize drag (or the aerodynamic force opposing forward velocity) and to produce forward thrust (Hedrick et al. 2002).

Pacific parrotlets (*Forpus coelestis*) are a small species (~26 g) of parrot that can serve as a useful model to understand psittacine wing morphing during flight. Psittacines refer to the sub-family, Psittacinae, in the family, Psittacidae, in the super-family, Psittacoidea. After takeoff, parrotlets and other parrots morph their wings to become aerodynamically favorable throughout flight. Upon takeoff, parrotlets push off horizontally using their legs to accelerate forward. During the first downstroke, parrotlets then rotate their tail downward, while simultaneously twisting and rotating their wings downward relative to their body. This allows an aerodynamically favorable lift upon takeoff. During experimental short 20 cm flights, parrotlets primarily used partial downstroke wingbeats to reach their destination. During longer 75 cm flights, parrotlets folded their wings mid-flight to produce flexed-wing bounds (Chin and Lentink 2017). Producing bounds necessitates high energy expenditure, and therefore is only used by birds <300 g (Tobalske 2007). While landing, parrotlets direct leg impulses horizontally against the air, with few winged upstrokes to assist in smooth deceleration (Chin and Lentink 2017).

Wing loading, typically measured as body mass (kg) / wing area (m<sup>2</sup>), is useful in understanding how different species within the Psittaciformes order adapt their flight to optimize aerodynamic variables and minimize energetic costs. For example, though both cockatiels (~70–120 g) and African grey parrots (~400 g) have a wingspan of ~33 cm, and likely similar wing areas, wing load varies significantly due to large differences in body mass (Holman 2008; Newmyer 2011). Assuming wing area remains constant, aerodynamic theory suggests that as body mass increases, wing load increases. Within the psittacines, there is significant variation in body mass and resultant wing load. For example, some birds of the *Poicephalus* genus can weigh ~120 g (comparable to the cockatiel), while others

can weigh as much as ~400 g (comparable to their relatives, *Psittacus* birds). By this principle, the African grey parrot (*Psittacus erithacus*) should have a higher wing load as compared to cockatiels. To compensate for their large mass, African grey parrots utilize vertical flight at slow speeds during foraging to travel between the ground and treetops. During the upstroke, wing elevators, such as *m. supracoracoideus*, forcefully contract to produce an upward aerodynamic force. Powerful wing retractors are needed to maintain this position, since the energetic cost of vertical flight is high. Muscle weight analysis across Psittaciformes and non-Psittaciformes has revealed that parrots have significantly bulkier *m. deltoideus pars propatagialis* to assist in vertical take-off and to maintain a negative angle of attack, or vertical body position (Razmadze et al. 2018).

In many regards, the flight mechanics of the parrots closely match those observed in pigeons (*Columba livia*), which have a mass (~370 g) more comparable to *Psittacus* and some *Poicephalus* birds (~400 g). In between flapping phases, pigeons and two species of Psittaciformes, including cockatiels, use intermittent extended-wing glides to reduce the aerodynamic power ( $P_{aero}$ ) required for flight. During slow flight, both pigeons and cockatiels utilize rolls during the downstroke to maneuver through turns. For example, a left turn is accomplished by asymmetric contraction of both pectoralis muscles. The result is higher velocity on the outer wing of the turn (right) during the initial downstroke. Termination of the roll involves switching the side of greater pectoralis force, causing higher velocity on the inner wing (left) midway through the downstroke (Tobalske 2007).

## Flight Energetics

Locomotor energetics can be best understood by comparing basal metabolic rate (BMR) to oxygen consumption during activity. Basal metabolic rate represents the oxygen consumption of an animal's tissues and organs at rest, and is proportional to total energy expenditure. A species' BMR is also significantly influenced by the environment it

inhabits and is adapted to. For example, red-tailed black cockatoos can exist in either arid or cool environments. Those adapted to arid environments have lower BMRs than those adapted to cooler forested habitats (Cooper et al. 2002). Disturbances to environmental temperatures, such as extreme heat or cold, force animals to exert energy to maintain thermal homeostasis. Psittacines in particular are adapted to living in warm tropical climates, and as such have low BMRs. Low resting energy expenditure assists in energy conservation by allowing more energy to be spent in foraging or flying, especially when resources are limited. The energetics of psittacines can therefore also be affected by a seasonally variable environment. For example, the burrowing parrot (*Cyanoliseus patagonus*) resides in the Patagonian region of Argentina, which tends to have an unpredictable climate with mild winters. Due to significant temperature variance, the burrowing parrot must exert extra energy to maintain thermogenic homeostasis. As a result, these psittacines have been shown to have variable BMRs depending on the season. During the winter, psittacine BMRs tend to decrease (on average 45%) as an energy conservatory mechanism. Reducing winter energetic costs is vital for the survival of such species, especially since food is scarce during colder months (Zungu et al. 2013). These adaptations are crucial for the survival of Psittaciformes, and ultimately dictate the energy expenditure allowed for locomotion.

Parrot flight demands high energy expenditure, and is therefore primarily reserved for travel between neighboring nesting sites. Anatomically, the pectoral muscles provide most of the mechanical power needed for flight, through multiple sustained contractions (Morris et al. 2010). Energy consumption in relation to flight speed for cockatiels and budgerigars (*Melopsittacus undulatus*) follows a U-shaped curve, in accordance with aerodynamic theory [i.e., the greatest energy consumption occurs at low and high speeds, while intermediate speeds require the least amount of energy (Bundle et al. 2007) (Fig. 2)]. Study of metabolic consumption during budgerigar flight has revealed that energy cost is also highest in ascending flight, followed by descending flight, and least in level flight. Oxygen

**Psittaciformes Locomotion, Fig. 2** Oxygen consumption ( $\dot{V}O_2$ ) in budgerigars (red triangles) versus cockatiels (blue squares) at varying flight speeds. (Data reproduced from Bundle et al. (2007) and Tucker (1968))

consumption, during level flight, was most economical at ~35 km/h. Researchers found that maintaining a speed of 42 m/s optimized energy consumption, while maximizing the distance covered (Tucker 1968).

As flight is an energetically expensive mechanism of travel, Psittaciformes have adopted several mechanisms to reduce this cost. As mentioned earlier, Pacific parrotlets push off using their legs during takeoff and accelerate up to ~80–100% of average flight speeds. Energetic studies have revealed that it is more efficient to use leg muscles during takeoff and landing, than to use multiple contractions of the pectoral muscles, as in flapping flight (Chin and Lentink 2017). Parrots, in particular, also conserve energy by incorporating gliding into their flight. A flap-glide pattern takes advantage of the bird's inertia to minimize the amount of power the pectoral muscles produce to maintain flight. When flapping, the pectoral musculature must use multiple concentric muscle contractions to produce flight, which requires more energy than the sustained isometric contractions used in gliding. Using this method, parrots are able to reduce the high energetic cost of flight (Bundle et al. 2007).

## Additional Locomotion Modes

In addition to flight, Psittaciformes utilize other locomotor modes such as hopping, walking, and climbing to travel short distances. These modes assist in energy preservation when foraging from the ground to the treetops. During foraging, Pacific parrotlets use similar energy conservation strategies as during flight takeoff and landing. To hop and walk, parrotlets rely on small horizontally directed leg impulses to travel across branches. Doing so reduces energetic cost as it relies on short infrequent bursts of energy, rather than alternating between many forceful and sustained contractions of the pectoralis muscle (Chin and Lentink 2017).

Climbing is another energetically favorable form of locomotion that parrots use for play, foraging, and exploratory behaviors. Unique to the parrots during climbing is the use of their hook-like maxilla, or beak, and zygodactyl feet to climb and manipulate objects (Demery et al. 2011). To accomplish this, they primarily use *m. ethmomandibularis*, which is derived from *m. pterygoideus*. *M. ethmomandibularis* is a dual-bellied adductor muscle that when contracted, causes powerful elevation of the lower jaw, resulting in a strong grip. This tight grip is essential for anchoring parrots to branches as they climb upward against gravity.

Parrots also use their zygodactyl feet to assist in climbing and hanging off of tree branches. Each zygodactyl foot contains intrinsic foot muscles (mostly flexors) to accomplish this. Toe orientation allows for dexterity, allowing handling of food by one foot and support of hanging body weight by the other. Muscle analysis studies of zygodactyl feet have shown that birds which rely on climbing for travel, such as psittacines and monk parakeets, have hindlimb muscles greater in mass than birds which rely on flight for travel. These studies once again support the theory that Psittaciformes prefer to use hopping, climbing, or walking to optimize

their locomotor energy consumption (Carril et al. 2014).

## Migration

The majority of Psittaciformes do not undergo typical large-scale seasonal migration, but rather are nomadic within a fixed geographical area, between nesting and feeding areas. Some examples of nomads include budgerigars, scarlet-chested parrots, night parrots, African grey parrots, blue-headed parrots, and Eclectus parrots. African grey parrots often travel daily between neighboring woodlands and prefer roosting in trees over water or on islands with rivers. Parrots rely on pine nuts as a main food source. Unpredictable food shortages can force migration from core areas of food distribution to surrounding areas with more favorable foraging conditions, as seen with the thick-billed parrot. Some rose-ringed parakeets (*Psittacula krameri*) reside in mountainous areas and move to lower altitudes during winter months to escape the harsh coldness. Few parrot species, such as the orange-bellied parrot and blue-winged parrot (*Neophema* genus), are inherently migratory birds. Both birds seasonally migrate between Tasmania and the Australian continent across the Bass Strait (Parr and Juniper 2010).

## Bioinspiration

Aircraft design and human flight has been greatly influenced by Psittaciformes locomotion. Researchers have found that at low speeds, cockatiels reorient their bodies and change their bank angle, or the angle of their wing relative to the horizon, to execute a turn (Hedrick and Biewener 2007). Experimentally to make a 90° turn, cockatiels established a bank angle of 60° and flapped through the turn. Aircrafts mimic this flight strategy of body reorientation and increasing bank angle to make quick or tight turns (Hedrick and Biewener 2007).

To efficiently move through the air, both birds and aircrafts must modify their structure to reduce drag. Both aircrafts and cockatiels at high speeds produce continuous vortices, and thereby significant drag from each wingtip. In cockatiels, vortices are a result of flapping flight, whereas in aircrafts, they are a result of fixed wing length. To reduce drag while flying, cockatiels will lay their crest, or the feathers on top of their head, flat against the skull. Although aircrafts do not have crests, engineers have installed winglets at the tips of aircraft wings to assist in both producing lift and reducing drag produced by the continuous vortices. These winglets parallel the function of winglets in soaring birds and cockatiels flattening their crest during flight to decrease drag and improve energy efficiency (Hedrick et al. 2002; Newmyer 2011).

Current commercial aircraft wings are manufactured as immobilized entities, which are unable to flap or change orientation in the same manner that birds' wings can. Avian biomechanists have sought to improve current aircraft technology by creating biohybrid robotic wings, which can morph shape, as occurs during Psittacine flight. Morphing of the wing requires overlapping feathers and the presence of three primary positions—flexed, mid-tucked, and extended. Wing morphing includes movement of discrete wing elements to change the overall shape of the wing. This maneuver has been shown to increase efficiency and agility during flight, while also allowing for faster and tighter turns. Using kinematic data from parrotlets and lovebirds, researchers have since created PigeonBot, 280 g biohybrid robot modeling pigeons. PigeonBot can mimic pigeon and psittacine gait patterns including rolling, turning, flapping, and morphing, even in turbulent winds (Chang et al. 2020).

Study of Pacific parrotlet flight adaptations have also been used to advance biohybrid wing morphing technology. During flapping flight, parrotlets use wing muscles and energy stored in tendons to fold their wings. Wing unfolding, on the other hand, occurs passively as a result of

centrifugal acceleration. Scientists have sought to model this phenomenon in biohybrid wings, by using tuned springs to mimic energy storage in tendons during wing folding. Wing morphing thereby reduces drag during the upstroke of forward flight (Stowers and Lentink 2015). Improvements to such bioinspired projects may in the future help transform the field of aircraft engineering to improve maneuverability and fuel efficiency.

## Conclusion

During flight, Psittaciformes gait is mostly classified by speed—vortex-ring gait is used at slow speeds ( $<7$  m/sec) and continuous vortex gait at high speeds ( $>7$  m/sec). Psittaciformes are foragers and rely on stable food availability within a relatively fixed geographical location. Given that many Psittaciformes are relatively heavy birds, they have adapted their locomotor preferences to fit energetic constraints. For example, to minimize energy expenditure, psittacines especially prefer to climb, hop, and walk when traveling short distances. Vertical flight, which allows birds to briefly pause mid-flight, is used for foraging between the ground and treetops. Study of Psittaciformes gait has also helped inform the development of new technologies, such as PigeonBot. Ultimately, by understanding avian locomotion and creating biohybrid robotic models to mimic their patterns, avian biomechanists could help transform and optimize current aircraft technology.

## Introduction

Parrots have a number of behavioral attributes that make them stand out from other bird taxa. In particular, they have a high level of manipulative skills, a life-long curiosity about new objects, and highly developed cognitive abilities. In addition, most parrot species are highly social, often coming together in large aggregations to roost and feed and fly in compact formations. In many species, long-term social bonds are formed, and some species are long-lived, even on a human scale.

These features, as well as their often colorful plumages, have made parrots a focus of fascination to humans, and they have been favored as pets since at least the time of the early Roman Empire.

About 400 species of parrots (Order Psittaciformes) are recognized currently. They are divided into three or four families depending upon the approach to systematics adopted. Parrots occupy a wide range of habitats, from rain forests to arid savannahs. Despite this diversity of environments, several aspects of their ecology are common to most taxa. The majority of species feed predominantly on the reproductive structures of plants (i.e., seeds, fruit, nectar), although some species can be considered omnivorous, due to their consumption of invertebrates.

Fruits and seeds tend to be highly clumped in time and space, and many aspects of the behavior of parrots, such as forming large social groups and long daily and seasonal movements, are likely linked to the need to track these ephemeral resources (Lopes et al. 2018). Nearly all parrots nest in cavities, often making use of naturally occurring holes in trees and cliffs, while some species excavate burrows or parasitize the nests of other species. Most species are primarily diurnally active although there are a few species (notably Kākāpō *Strigops habroptila*, night parrots *Pezoporus occidentalis*) that are primarily nocturnal.

The dextrous manipulatory abilities of parrots are typically based around extracting embedded food items (Fig. 1), but they also readily explore nonfood items. These skills are made possible by distinctive morphological adaptations of their feet, bills, and tongues. Their feet are zygodactyl (two toes face forward and two back), an arrangement that allows objects to be grasped securely. All parrots have a highly curved upper bill and a thick muscular tongue. The maxilla (bone of the upper mandible) is joined to the skull by a synovial hinge joint and this allows movement of the upper as well as the lower jaw. The ability to articulate the maxilla is unique to parrots as in all other birds the maxilla is fused to the skull.

**Psittaciformes Sensory Systems, Fig. 1** A grey parrot *Psittacus erithacus* extracting seed from a palm fruit. The fruit is held in the zygodactyl foot and manipulated by the bill and tongue. The eyes are placed high in the skull and on the sides of the head. This gives the bird extensive visual coverage of the world about it, and two areas of high visual resolution occur on each side of the head. However, the bird can only just see what is held in its bill. Manipulation of the food item is controlled by a touch-sensitive bill-tip organ. (Photograph R. O. Martin/World Parrot Trust)

A particularly notable feature of parrots is their ability to use the bill as a “third limb.” They do this while climbing both up and downward through complex vegetation or across solid surfaces, such as tree bark, rock, and soil.

To express their full range of manipulative and climbing skills, and their complex social behaviors, parrots require a constant stream of accurate information about their environment. This includes information on the positions of close and remote objects, information about objects held in the bill and mouth, and information about the positions of others in a flock.

Information is extracted from the environment by the senses, and it is now clearly understood that all animal species have a “sensory ecology” that describes the specific and general relationships between an animal’s behavior and the information used to control it (Martin 2017a). Furthermore, it is now evident that an animal’s senses are as much subject to fine tuning through natural selection as

are its morphological features. While morphology is tuned to the physical challenges posed by the conduct of different tasks in different environments, the senses are tuned to the sensory challenges that these tasks and environments pose. In essence, morphological features can be regarded as the tools with which animals interact with their environment, while the senses provide information for the efficient guidance of those tools. Senses also provide information that ensures individual safety. These include the screening of food items, the detection of predators, and the detection of damage to the body.

One result of this natural selection of sensory information is that senses can vary between species just as much as morphology. Even closely related species can differ in their senses and in the information that they extract from the environment. No species is “all-seeing” or “all-hearing” any more than it can have a bill or a foot that allows it to do all manner of physical tasks. However, while morphology can be readily described and measured, information on senses is less accessible and so the diversity of senses within a taxon is usually less well cataloged and understood. Fortunately, broad descriptions of sensory capacity, and of the information that they provide, are available for most animal groups. In many taxa, some aspects are known in more detail than others, and this is the case among parrots.

### The Senses of Parrots

The telereceptive senses function primarily to gather information about objects remote from the animal. They provide the bulk of information used to orient an animal within its physical and social environments. The intimate senses provide information about objects and substances that are in physical contact with the animal.

In parrots, as in other birds, two telereceptive senses are key: vision and hearing, and it is possible to describe them in broad terms that will apply to most species. Vision is, however, a multifaceted sense and impossible to describe succinctly. Furthermore, it is probably true that vision is not exactly the same in any two species of birds and there are likely to be subtle specializations between parrot species as well as

differences between parrots and other bird taxa. Hearing in parrots is perhaps less specialized, showing characteristics shared among many other bird species.

The sense of smell is also telereceptive, and in parrots, it may be similar to that of other birds. It is likely to provide important information in some, if not all, species of parrots. Magnetoreception, the extraction of information from the Earth's magnetic field, is perhaps best regarded as telereceptive. It does not, however, provide information about distant objects. Rather it provides information about the magnetic environment in which an animal is situated, and this is used to help orient the animal at various spatial scales. Magnetoreception has not been directly demonstrated in parrots but it may well be widely distributed among birds of various orders and could play a role in guiding both long and short distance travel in parrots.

Among the intimate senses, the sense of touch is highly specialized in parrots. From one perspective touch could be considered a key sense of parrots. This is because it is crucial in the control of some of parrots' most distinctive and intriguing behaviors, especially object manipulation and climbing using the bill. Taste provides information on substances within an animal's mouth and gut and is therefore the ultimate intimate sense. Little is specifically known about taste in parrots but, as in other birds, it probably plays a crucial role in the selection of food items.

## Vision

The primary reliance of parrots on vision is easily asserted. It can be based upon casual observation of parrots completing their everyday behaviors, and it is supported by evidence that relatively large portions of parrot brains are devoted to the analysis of information from vision (Iwaniuk and Hurd 2005).

Vision is a difficult sense to investigate because there are many aspects to the information that vision provides. These include the breadth of the visible spectrum, the presence and subtlety of color vision, the accuracy of spatial resolution at different light levels, differences in the directions about the head in which vision is most acute, and

the total volume about the head from which information can be extracted at any moment.

## Spatial Resolution

Spatial resolution (the ability to resolve detail in a scene) varies markedly across animal species. Acuity is often used as a benchmark of spatial resolution in a species. However, acuity captures only one specific attribute of visual performance. It is a measure of the highest resolution possible by an eye and refers to the situation when the stimulus is a high contrast (black and white) regular pattern of stripes, viewed under light levels equivalent to bright sunlight. Acuity defines the upper limit of the detail that can be detected in a scene. It is best determined using behavioral training methods, but it can be estimated from knowledge of the focal length of the eye's optical system, and the spacing of photoreceptors, or retinal ganglion cells, in the region of the retina where they occur at their highest density.

The highest acuity recorded in any animal species is that found in eagles (Accipitriformes) and equals 0.2 min of arc (142 cycles/degree) (Table 1). This is about twice that of the best acuity recorded in young humans and five times better than the acuity of an older person (Martin 2017a). This means that an eagle could detect a given target at twice the distance at which it first becomes visible to a young human, or five times the distance of an older person. Acuity in parrots is considerably below the performance of eagles or humans. Behaviorally measured acuity was found to be about 2.6 min in Budgerigars *Melopsittacus undulatus* and 3.2 min in Bourke's Parrots *Neopsephotus bourkii* (Lind et al. 2012). Thus, spatial resolution in these parrots is 13–16 times lower than in eagles and perhaps 3 times lower than an average mature human. The spatial resolution of these parrots is, however, not exceptionally low among birds and is, for example, similar to that found in species of doves, passerines, ducks, and geese (Martin 2017a).

A useful context in which to view this difference in spatial resolution between parrots and eagles is to consider that in eagles, vision is primarily used for detecting larger objects at great distances when hunting. This is a visual task that

**Psittaciformes Sensory Systems, Table 1** The highest spatial resolution reported in a sample of bird species, and in young humans. Resolution is shown as both cycles/degree and minutes of arc. The two measures are interchangeable; older studies tended to use acuity while more recent studies prefer to express resolution in cycles per degree. In some species the highest resolution has been estimated from knowledge of the eye’s size and the spacing of retinal ganglion cells at their highest density (see Fig. 3). Behavioural measures were determined by training birds to

make discriminations which indicate the finest spatial detail that can be resolved using high contrast patterns viewed under high, day-time light levels. To compare between species simply divide their acuity values. Thus, the eagle’s spatial resolution is about 8 times higher than that of a dove, 13 times higher than a budgerigar, and 30 times higher than a sparrow. Expressed another way, an eagle should be able to detect a given object eight times further away than a dove, and 13 times further away than a budgerigar

| Species                                     | Spatial resolution<br>Cycles/degree | Acuity<br>Minutes of arc |
|---------------------------------------------|-------------------------------------|--------------------------|
| Wedge-tailed Eagle <i>Aquila audax</i>      | 142                                 | 0.2                      |
| Brown Falcon <i>Falco berigora</i>          | 73                                  | 0.4                      |
| Rock Dove <i>Columba livia</i>              | 18                                  | 1.7                      |
| Budgerigar <i>Melopsittacus undulatus</i>   | 11.7                                | 2.6                      |
| Canada Goose <i>Branta canadensis</i>       | 9.6                                 | 3.1                      |
| Bourke’s Parrot <i>Neopsephotus bourkii</i> | 9.4                                 | 3.2                      |
| Great Horned Owl <i>Bubo virginianus</i>    | 7.5                                 | 4                        |
| House Sparrow <i>Passer domesticus</i>      | 4.8                                 | 6.3                      |
| Human (young)                               | 72                                  | 0.4                      |
| Human (mature/with spectacles)              | 30                                  | 1.0                      |

parrots are not interested in. Parrots are primarily interested in relatively large objects that are nearby and so it seems likely that their acuity matches the visual challenges of such tasks. Basically, there would be no selective pressure to evolve higher spatial resolution.

Although acuity can be readily compared across species, spatial resolution is not a fixed value. It is highly dependent on light level, the position at which it is measured within the visual field, the color, and the contrast within stimulus patterns. Natural stimuli are often of low contrast and may be colored, furthermore visual tasks are commonly undertaken at low light levels. In birds, spatial resolution has been shown to decline markedly with light level in a range of species, and this is true of parrots (Lind et al. 2012). Contrast sensitivity in Budgerigars is lower than in hawks, eagles, and falcons but similar to that of doves and owls (Fig. 2). Even under high light levels, acuity measured with colored stimulus patterns is lower than with black and white patterns (Potier et al. 2018). Although this has not been investigated in parrots this is likely to be the case in these birds. It means that color vision is best suited for discriminating between relatively large

patches at close range rather than detecting fine spatial detail at a distance.

Spatial resolution varies markedly within the field of view of an eye. Typically, in bird eyes, there is a region within the retina where photoreceptor and ganglion cell densities are highest, with density falling away from those regions. The result is that spatial resolution is much lower in the peripheral region of each eye’s field. This is certainly the case in Budgerigar eyes; retinal ganglion cell density is highest in a central region of the retina (Mitkus et al. 2014) (Fig. 3). Some Budgerigars have been shown to have a second region within their retinas in which the density of ganglion cells is elevated (Mitkus et al. 2014). These regions project backward within the field of view and the elevated acuity associated with them may play an important role in the detection of predators and conspecifics.

Spatial resolution has also been found to differ between the two eyes in some species of parrots. While the pattern of distributions of retinal ganglion cells in the left and right eyes are similar their densities have been found to differ significantly, with much higher densities in the left eye (Fig. 4). Such asymmetry between the eyes has

**Psittaciformes Sensory Systems, Fig. 2** Contrast sensitivity functions of birds, cats, and humans. All functions show the same general shape. However, differences in the positions and height of each of these curves indicate that each species can extract information from a different range of spatial frequencies and contrasts. Humans and cats are more sensitive to contrast than any of the birds, and they

can extract information over a broader range of spatial frequencies than any of the birds. Budgerigars can detect information only from a range of lower spatial frequencies compared with diurnal raptors, but their spatial vision is similar to that of doves and owls. (Redrawn from an original figure by Simon Potier of the Lund University Vision Group)

P

**Psittaciformes Sensory Systems, Fig. 3** The pattern of ganglion cells' distribution in the retina of a Budgerigar. This is an isodensity contour map, and numbers indicate the density of ganglion cells in 1000s per mm<sup>2</sup>. In this Budgerigar's retina, there are two areas of high cell density. Each provides a region of enhanced visual acuity in the

bird's visual field. The central area looks out toward the viewer from the eye of the Budgerigar as shown in the photograph. The lateral area lies toward the bird's bill and looks backward within its visual field. (Redrawn from original diagrams by Mindaugas Mitkus, Lund University Vision Group and from Martin 2017a)

**Psittaciformes Sensory Systems, Fig. 4** Left-right eye asymmetry in the patterns of ganglion cell distributions in the retinas of red-tailed black Cockatoos and Carnaby's

black cockatoos. Numbers on the isodensity lines indicate the density of ganglion cells in 1000s per  $\text{mm}^2$ . (From Coimbra et al. 2014)

been found in Carnaby's Black Cockatoos *Zanda latirostris*, Red-tailed Black Cockatoos *Calyptorhynchus banksia*, Long-billed Corellas *Cacatua tenuirostris*, and Little Corella (*C. sanguinea*). This asymmetry indicates that spatial resolution in the left eye is higher than in the right eye. These

differences have been functionally linked to the preference in these birds of using the left foot to hold, and the left eye to inspect, objects. Such asymmetry between the eyes is not found in all parrot species. The same study showed no left-eye right-eye asymmetry in Galahs *Eolophus*

*roseicapillus* or Cockatiels *Nymphicus hollandicus*, species which do not show strong eye preferences (Coimbra et al. 2014).

### Color Vision and Ultraviolet

It is highly likely that parrots have color vision and can discern small differences within the spectrum. Like most birds, parrot retinas have six photoreceptor types (rods, double cones, and four types of single cones) (Martin and Osorio 2008). Rods function at lower light levels and do not provide color discrimination, double cones probably function to provide luminance information, and the four types of single cones underlie color vision. Each type of cone contains a specific photopigment and oil droplet combination (Fig. 5). Although each receptor type covers a relatively narrow part of the visible spectrum, together they give parrots vision across a broad spectrum of light frequencies. Definitive color vision tests have not been done in parrots, but the similarity of their suite of photoreceptors to those of birds in which such tests have been conducted suggests strongly that parrots can make fine discriminations. Given what is known of the physiology, ecology, and behavior of parrots it is unlikely that parrots are exceptional among birds in their fine color discrimination, but they are likely to be better than most mammals, including humans.

The visible spectrum of parrots shows a strong parallel with those of the songbirds (Passeriformes) (Hunt et al. 2009). Parrots and passerines are considered sister taxa, that is, they are more closely related to each other than they are to other birds and share a common ancestor. Both parrots and passerines are exceptional among birds, apart from gulls (Laridae, Charadriiformes) and ostriches (Struthionidae, Struthioniformes), for having a type of cone photoreceptor which has maximum sensitivity in the ultraviolet (UV) part of the spectrum. This means that parrots can potentially gain information from UV patterns in plumage, foliage, and fruits that other nonpasserine birds (and humans) are unaware of. In some parrot species, there are plumage patterns that show up in the UV part of the spectrum, patterns that human eyes cannot detect and which can

convey important information about species, sex, and possibly health (Berg and Bennett 2010).

### Visual Fields

In parrots, as in all birds, the eyes are positioned on the side of the head. Each eye looks in a different direction with little overlap in their fields of view. This arrangement results in a much more comprehensive view of the world at any moment than is the case in humans. The result of the lateral placement of eyes is that birds in effect flow through their visual world; objects are seen in front, and they flow past and disappear slowly from the view behind (Martin 2017b).

Another important consequence of birds' laterally placed eyes is that the direction of best resolution lies not in front (as in ourselves), but to the sides of the head. This means that parrots have two separate areas of high resolution, to the left and to the right of the head. For parrots, as in many other birds, examination of an object in detail involves looking laterally with one eye only, not examining it with frontal vision. Parrots are frequently seen to turn their heads to peer at something laterally, apparently taking a "sideways look" at an object, but they are in fact examining it with their highest resolution vision.

In Senegal parrots *Poicephalus senegalus*, it has been possible to show that they have a vertically long and horizontally narrow binocular field (Fig. 6) (Demery et al. 2011). Its maximum width is 27° in the horizontal plane, but it extends vertically through 180° (there is binocular vision directly above the head) and there is a blind sector only 16° wide directly behind the head. This means that only small head rotations are necessary to achieve comprehensive scanning of the scene above and behind the head. Because the eyes are positioned high on the sides of the head, a bird can only just see its bill tip.

It seems likely that the arrangement of the visual field in Senegal parrots is typical of most other parrot species. It means that parrots can be continually vigilant for approaching predators and also be aware of others in their social group, even when they are foraging or manipulating objects with their bill and feet.

**Psittaciformes Sensory Systems, Fig. 5** The different types of photoreceptors found in the eyes of parrots (and passerines). The sensitivity in the spectrum of each cone type is shown in the lower part of the diagram. Parrots have four types of single cones whereas most mammals, including humans, have three. The lower part of the diagram indicates that the visible spectrum in parrots is broader than in humans. This is due to the presence in parrots of a cone type which has sensitivity that extends into the ultra-violet. However, in both humans and parrots, visual sensitivity is similar at the red end of the spectrum. The rod

receptors in parrots, and in most animal species, have a very similar sensitivity centered upon the green part of the visible spectrum. The four types of single cones underlie color vision and are each sensitive to a narrow part of the spectrum. The double cones, which underlie the detection of luminance (brightness), have a broad range of sensitivity extending from the blue to red portions of the spectrum. (Based upon illustrations by Peter Olsson (Lund University Vision Group) and Daniel Osorio (University of Sussex, UK) and from Martin 2017a)

**Psittaciformes Sensory Systems, Fig. 6** The visual field of a Senegal parrot. The top left diagram shows the field as seen projected onto the surface of a sphere surrounding the bird's head. The lower diagram shows a horizontal section through the visual field along the line a–b indicated in the sketch of the bird's head. The projection from the eye to the bill-tip is depicted. The diagram indicates that parrots have a narrow and vertically long binocular field and a very extensive monocular field to each side of the head. The extent of the binocular field in the vertical (median sagittal) plane of the head is also depicted in the two lower diagrams. On the lower left, a

bird is shown walking across a flat surface approaching an object. Even with the head lowered, so that the object lies in the broadest section of the binocular field, the birds can see almost the whole of the sphere surrounding its head, just a small rotation of the head is necessary to scan the world behind. When holding an object in the bill, a parrot – shown perching in the lower right diagram – can still see extensively above and behind, but it can only just see the object held in the bill. Also see Fig. 1 showing a photograph of a parrot manipulating an object. (Redrawn from illustrations in Demery et al. 2011)

Parrots' ability to only just see the tip of their bill is quite different to the situation in many other birds. In many species, the bill projects more or less centrally in the region of binocular vision

(Martin 2017b). This arrangement is used to direct the bill with high accuracy toward a target and to time its arrival there with precision. This arrangement is the key to accurate pecking and lunging

with the bill and is also used for catching prey with the feet which are brought up into the binocular field when pouncing on prey (e.g., in raptors). Parrots do not feed by pecking or lunging at items guided by vision. Like other birds which have near comprehensive vision about their heads, such as some shorebirds and ibises (Martin 2017b), the foraging of parrots is aided by touch sensitivity at their bill tips (see section on “Touch” sensitivity below). Having near comprehensive vision may also be important in the flock behaviors of parrots, allowing accurate spacing and coordinated flight movements.

### Temporal Resolution

Temporal resolution of vision is usually investigated by determining the flicker fusion frequency (FFF). This is the frequency of a flashing light, at which the eye can no longer distinguish a flickering light from a constant light of equal intensity. It has been determined both behaviorally and physiologically. High temporal resolution, well in excess of that of humans, has been described in some species of small songbirds. Such high FFFs have been interpreted as associated with the need to detect detail when moving rapidly in complex environments. Like spatial resolution, temporal resolution is a function of light levels with highest FFFs occurring at higher, daytime, light levels. The flicker fusion frequency of Budgerigars has not been found to equal those of small songbirds. At typical daytime light levels, the FFF of Budgerigars is similar to those of humans, with a flicker fusion frequency of 82 Hz (Bostrom et al. 2017). Based upon this it has been concluded that Budgerigars, and possibly other parrot species, are unable to detect the flicker of artificial lights that use fluorescent tubes or lamps with incandescent filaments.

### Hearing

Hearing has been investigated in detail in some parrot species and most extensively in Budgerigars (Dooling et al. 2000). The frequency range of hearing and the hearing sensitivity of parrots is similar to those of other birds, there being only relatively small differences in hearing across a wide range of bird species (Dooling et al. 2000;

Fay 1992). The frequency range of parrot hearing is narrower than that of humans and it seems that the hearing of nearly all birds sits within the overall envelope of the hearing of young humans (Fig. 7). This indicates that whatever sounds a parrot can hear, a young human will be able to detect. Parrots can hear sounds within a frequency range of about 200 Hz–8 kHz (Heffner et al. 2016), this compares with the young human frequency range of 20 Hz–20 kHz. In both humans and parrots, the maximum sensitivity to sounds occurs in the 1–4 kHz range, which is roughly the frequency range of the notes on the upper half of a piano keyboard. The hearing range of humans narrows with age, with hearing loss primarily in the higher frequency ranges. This suggests that the frequency range of hearing in aging humans may become more similar to that of a parrot. Whether the longer lived parrots also suffer hearing loss with age is not known.

### Sound Location

The ability to locate sounds in both direction and distance (sound range) is important in determining just how useful sound can be as a means of gaining information from the remote environment. While the simple detection of a sound may be useful, knowing the direction from which it came and how far away the source is adds considerably to the utility of that sound information. Evidence shows that in most birds these abilities are rather poor, especially compared with humans who can determine the direction of a nearby sound source, to within one or two degrees (Klump 2000). Humans are also able to learn to determine the range of nearby familiar sounds within a few meters, but this is a learned cognitive ability and requires repeated exposure to similar sounds under a range of acoustic conditions.

The poor sound location found in the majority of birds is attributable primarily to physics. Ear openings in parrots are hidden by a small group of feathers (ear coverts) and are situated just behind and below the eyes. Because of the relatively narrow heads of parrots, the ear openings are separated laterally by only a small distance. The consequence of this is that there are only very small differences in the timing and intensity of

**Psittaciformes Sensory Systems, Fig. 7** Audiograms of a young human and a Budgerigar. Hearing sensitivity in both species shows the typical U-shape of audiograms found in most animal species. Sensitivity falls gradually as sound frequency decreases but there is a more rapid decrease in sensitivity as sound frequency increases. Both

species are most sensitive to sounds between 2 and 4 kHz. The audiogram of the parrot sits wholly within the human audiogram indicating that all sounds that a young human can hear can also be heard by the Budgerigar, and that there are sounds which humans can hear that parrots are unable to detect. (Redrawn from Heffner et al. 2016)

sounds arriving at each ear. It is these differences that are used to determine sound direction in the horizontal plane. The larger these differences, the more accurately sound can theoretically be located. It is the large solid head, widely separated ears, and the elaborations of the outer ears that give humans the advantage over parrots and other birds when trying to locate a sound.

Owls (Strigiformes) are the only group of birds which can match human sound localization accuracy, and they use this ability to locate hidden prey from a static location (Knudsen and Konishi 1979). This ability is primarily attributed to the elaborate outer ear structures that among birds are unique to owls. It seems that most birds, including parrots, would receive no selective advantage from such high accuracy of sound localization or sound ranging. This is because parrots do not use sound for prey location and because they are also highly mobile. Parrots can move rapidly in the

general direction of a sound that they find interesting and home in on it through successive approximations. There is no need to have a highly accurate fix upon the sound source before deciding to investigate it.

There have not, however, been any direct investigations of sound location or ranging in parrots, but it seems unlikely that they will have accuracy that is higher than in passerines. For example, Common Starlings *Sturnus vulgaris* can locate sound direction to within only 20 degrees (Feinkohl and Klump 2013), and Common Chaffinches *Fringilla coelebs*, seem to range sounds only into broad near (closer than 40 m), far (further than 80 m), and intermediate distance categories. The flightless nocturnal parrot Kākāpō *Strigops habroptila* uses sound to locate mates at long distances, and then approach them slowly on foot. Whether Kākāpō are able to determine the direction and

range of these calls with high accuracy is not known, but it is worth noting that the birds tend to move around their home ranges using pre-defined trackways, and this may obviate the need for accurate location and range.

### Smell

The sense of smell is often overlooked in birds. Like vision and hearing, smell is a telereceptive sense providing information about properties of the environment that are remote from the animal. There is increasing evidence that smell plays a vital role in the behavior of many bird species, especially in the location of potential food sources. Well-studied examples include petrels *Procellariidae*, Turkey vultures *Cathartes aura*, Oilbirds *Steatornis caripensis*, and kiwi *Apterygidae* (Martin 2017a). It is now becoming clear that smell is also used by a wide range of birds to mediate social interactions based primarily upon secretions from the uropygial gland. Species in which this has been demonstrated include chickens *Gallus gallus*, auks *Alcidae*, some passerines, and Budgerigars (Zhang et al. 2010).

That smell may function in the location of food sources has been demonstrated in some species of passerines (Amo et al. 2013). In view of the relatively close phylogenetic relationship between passerines and parrots, it is possible that the sense of smell could play an equally important role in parrots. Many parrot species rely on locating ephemeral food sources, such as fruiting trees, which can be highly variable in time and space, and the ability to detect food patches using smell would bring clear advantages. However, experimental investigations of the role of smell in food location in parrots do not seem to have been conducted. One intriguing example of a parrot using smell in the location of food comes from the observation of a Kākāpō which was shown able to use odor cues to locate hidden food (Hagelin 2004). Whether using smell in this way is part of Kākāpō natural behavior is not clear, but the fact that they can latch onto and exploit odor cues does suggest that smell is important to these birds, and possibly to other parrots.

### Taste

The taste system of birds can be viewed as a group of nutrient sensors which have evolved to evaluate the quality and nutritional content of foods, primarily at the point of ingestion, but also at various points within the gut (Berkhoudt 1985). Nothing is known specifically about taste in parrots, but it is probable that, like other birds, parrots use taste information to assess each item of potential food taken into the mouth cavity. Thus, taste functions as a sampling or screening process that detects the presence of specific groups of chemical compounds. Much of what is known about taste in birds comes from studies of domesticated breeds, notably chickens, ducks, and turkeys (Berkhoudt 1985).

The receptors of taste in birds are of relatively few types, but they can be numerous and occur in different concentrations in different locations within the body. The distribution of taste receptors in the mouths of birds follows the ingestion pathway. This allows items taken into the mouth to be rapidly screened for a range of chemical properties before entering the gastrointestinal tract.

In all vertebrates, taste signals are generated in taste buds. These are flask-shaped pits embedded mainly within the skin of the tongue but also in other structures within the mouth. Each taste bud contains groups of receptor types that detect the presence of specific chemical compounds. Like other sensory receptors, taste receptors have a long evolutionary history and show basic uniformity of structure and function across diverse animal groups. Taste receptors in the gut are probably involved in many aspects of sensing foods as they are digested and may trigger vomiting following the ingestion of a noxious substance.

In all birds so far investigated, taste receptors occur on the tongue, particularly toward the back, but they do not occur widely over the upper surface of the tongue, as is typical in mammals. It is highly likely that a similar distribution of taste receptors in the mouth cavity occurs in parrots (Berkhoudt 1985).

It seems likely that birds have at least seven distinct tastes (Martin 2017a). Five tastes function primarily in driving appetites for particular nutrients, and two tastes function primarily to provide

warning signals about items that are likely to be detrimental to health. The well-established “appetite tastes” of birds are sweet, umami (or amino acids), and salt, and these seem to drive the acquisition of foodstuffs. Less well-established appetite tastes are calcium and fat. Calcium may function particularly during breeding when calcium intake in females may need to increase to ensure the development of eggshells. Evidence for a specific fat taste, or fat detector mechanism, in birds is not well established but may be a feature of bird species. Bitter and sour receptors are regarded as providing “warning tastes,” which indicate substances that are likely to be harmful and should be rejected before or post ingestion.

### Touch

The configuration of the visual field in parrots precludes them from guiding the bill with high accuracy using visual information (see section on “Visual Fields”). Parrots are, however, noted for their manipulation of objects using their bill and for their use of the bill as a third limb when climbing. This control of the bill relies upon the sense of touch, specifically from a specialized collection of touch receptors positioned within the keratin of the rhamphotheca in the curved tip of the upper bill.

This collection of touch receptors is known as a “bill-tip organ” and is one of three types of bill-tip organs that occur in birds (du Toit et al. 2020). In ibises (Threskiornithidae), shorebirds (Scolopacidae), and kiwi (Apterygidae), the bill-tip organ consists of groups of touch/mechanoreceptors (Herbst corpuscles) that are embedded within densely clustered pits in the bone at the tip of the bill and are beneath the soft keratin that covers the bill tip. In ducks and geese (Anseriformes), a different type of bill-tip organ also employs Herbst corpuscles but they are grouped in “touch papillae” which extend through the hardened rhamphotheca which occurs around the bill tips in these birds (du Toit et al. 2020). Both of these types of bill-tip organs function primarily in the detection of food items hidden in leaf litter and soil, or in water-filled substrates, such as mud and sand.

In the bill-tip organs of parrots, the mechanoreceptors are arranged in discrete clusters around

the edge of the rhamphotheca of the upper bill. The parrots’ bill-tip organ is not used for the detection of hidden food items, but rather to guide the manipulation of food items. The bill-tip organ of parrots was first described in 1896 (Goujon 1896) but has only recently received further investigation, and is yet to be fully understood (Demery et al. 2011).

Figure 8 shows the bill-tip organ in a Senegal parrot. The touch receptors are clusters of primarily Herbst Corpuscles housed in pits in the keratin of the bill. The clusters are arranged symmetrically in seven pairs situated just inside the edges of the bill. There is a further single cluster of touch receptors at the bill tip. This arrangement gives a parrot detailed touch information about objects grasped between the bill tips. This information allows a parrot to manipulate and position an object without seeing it. The bill-tip organ provides information on the position, mechanical and surface properties of the grasped object. Many parrots are primarily seed predators and have powerful bills that enable them to feed on large hard-shelled seeds. For example, Great Green Macaws *Ara ambiguus* are highly dependent upon the seeds of Mountain almonds *Dipteryx oleifera*, which are large (60–80 mm × 40 mm) and very hard. Opening the seed case depends upon accurate positioning of the seeds in the bill, and this must be achieved using touch sensitivity since once in the mouth the seed cannot be seen.

This ability to open seed cases and examine food items using their bill-tip organ probably enables parrots to exploit food sources unavailable to other bird species. It is also possible that touch sensitivity plays a role in the transfer of regurgitated food from males to females during the incubating and brooding periods.

Another important function of the bill-tip organ in parrots may be that it provides touch information which allows parrots to use their hooked bill as a “third limb” when climbing about. Many parrots nest inside deep cavities and will use their bill to climb in and out of these cavities as well as for maneuvering around other environments such as within branches. Touch information from the bill-tip probably allows a parrot to assess the mechanical

**Psittaciformes Sensory Systems, Fig. 8** The bill-tip organ in a Senegal parrot. The touch-sensitive receptors are arranged in clearly visible discrete clusters along the

edges of the upper bill within the curved section of its tip. (From Martin 2017a)

characteristics of a grasped object, and thus allows the bird to confidently rely on what it is grasping when climbing.

As in other birds (Gottschaldt 1985), touch receptors (Herbst and Grandry corpuscles) in parrots are likely to be found distributed across much of the body surface, and around skeletal joints. They probably function to provide information on the position of limbs and feathers, as well as information about objects in contact with the body surface. However, the distribution of touch receptors across the body has not been investigated in detail in parrots.

### Magnetoreception

Magnetoreception is the ability to detect properties of a magnetic field. Magnetic fields vary in both strength and direction with respect to the

object that generates the field. The magnetic field of the Earth (the geomagnetic field) varies continuously and variations in strength and direction are potentially a rich source of information about position on the Earth and direction toward other positions. A large body of research indicates that birds are among the animal groups that can detect the geomagnetic field and potentially use it to determine position and guide travel. However, the actual mechanisms employed by birds to detect magnetic fields remain elusive.

It seems possible that in birds more than one mechanism is involved, providing magnetic information separately on direction and strength. The mechanisms also appear to be tuned to detect magnetic fields of the strengths that occur at the Earth's surface. One detection system may be

based in the eyes and provides information on field direction; the other mechanism is associated with the nostrils and the nerves that lead from them and provides information on field strength (Beason and Wiltschko 2015; Munro et al. 2014; Wiltschko and Wiltschko 2013).

Although the sample is small, the range of bird species in which detection of the geomagnetic field has been shown to exist is drawn from a wide taxonomic sample and includes pigeons, chickens, and songbirds. It has also been shown that detection of these fields can influence the orientation behavior of these birds. This suggests that magnetoreception may be widely distributed across bird species and may provide a source of information used to guide movements at different spatial scales. It is possible, therefore, that parrots could be counted among the species that can use geomagnetic information, but experimental evidence is lacking. However, some parrot species migrate and many species range over large areas (Collar 1997). To do this, individuals need to know where they are and the direction toward where they want to go. Magnetoreception may provide a source of information that helps parrots to do this, but definitive evidence is lacking, although it has not been sought.

## Psittacine Cognition

Gisela Kaplan

School of Science and Technology, University of New England, Armidale, NSW, Australia

## Introduction

The parrots of the world have always delighted humans for their stunning plumage, their playful nature, and their ability to mimic human speech and form friendships with people. Importantly, many, not all of them, belong to a group of birds with the largest brain to body weight ratio, and some are even on a par with primates. Brain weight or size is measured relative to body weight or size.

The order of Psittaciformes is the third largest group of birds. According to the International Ornithology List of Birds (Gill et al. 2021), the order Psittaciformes consists of 398 extant species belonging to 87 genera, and within it, one might distinguish three super families: the Psittacidae (“true” parrots), about 350 species worldwide, 40 of which are in Australia; the Cacatuidae (cockatoos), 22 species (14 within Australia); and the Strigopidae (New Zealand parrots) with five species, all endemic to New Zealand. Neotropical (South and Central American) species include the subfamily of Neotropical Arinae, which includes macaws, aras, and Amazon species. Further, across the entire range of southern continents, there are a large number of diverse parrots, the true parrots, and finally the groups of parakeets, lorikeets, and lories. In a recent resurgence in systematic studies of parrots, Joseph and colleagues (2012) proposed a revised nomenclature and classification for family-group taxa of parrots, and they have

advocated that all the various groups be subdivided into three superfamilies: Strigopoidea (New Zealand) Cacaoidea (all cockatoos), and Psittacoidea (for all remaining parrots).

Parrots are species of the southern hemisphere, or they are equatorial, meaning that most of the equatorial species extend 23.5° latitude to the north (the Tropic of Cancer) and 23.5° south (to the Tropic of Capricorn) which, however, does not imply that parrots are restricted to tropical or subtropical regions or to forests. They also live in the temperate zones of the southern continents, and some, such as the ringneck, *Barnardius zonarius*, and princess, *Polytelis alexandrae*, parrots of Australia or the burrowing conure, *Cyanoliseus patagonus*, of southeastern Patagonia, are even desert dwellers, but only two psittacines are cold-climate specialists – one is the austral or emerald parakeet, *Enicognathus ferrugineus*, of southern Patagonia (South America) and the other the kea, *Nestor notabilis*, of New Zealand, the only mountain parrot in the world (Fig. 1).

In 2008, a molecular study was published in support of a Gondwanan origin of parrots during the Cretaceous Period (Wright et al. 2008). Gondwana is the name of the continent that contained Africa, Australia, Antarctica, and South America. Some psittacine species, such as the Australian

cockatoos, are thought to have an evolutionary history of 95 mya (Wright et al. 2008), of importance in so far as these time frames go together with a number of considerable climate changes and ice ages, eventually leading to a drying out of the Australian continent. Over millions of years, these changes demanded substantial adaptations from flora and fauna.

The 22 species of cockatoos are split into the black cockatoos (*Calyptorhynchus* spp.) and the white cockatoos (*Cacatua* spp.). The species of cockatoos outside Australia are distributed on island populations northeast of Australia (Papua New Guinea and the Solomon Islands) and also north/northwest (indigenous to Tanimbar Island), such as the Goffin cockatoo or, more appropriately called, the Tanimbar corella (*Cacatua goffiniana*). Today, many species of parrot are on the endangered list either because of ongoing and large-scale habitat destruction (largely of forests) or because such species are being poached and traded as valuable export items. The result has been an accelerating slide toward extinction. Indeed, almost half of all parrots are listed on the list of endangered species, of which nearly 100 species are either critically endangered or in the highly endangered category (IUCN Red List of Threatened Species) – as compared to 13% of

**Psittacine Cognition, Fig. 1** Distribution of parrots throughout the world (marked red). The areas include tropical, subtropical, temperate, desert, and mountain

climates. The “oriental” bird region is delimited in the north by the mountain range of the Himalayas

birds worldwide. This is despite their long evolutionary history, their adaptability, and the discovery of the relatively large brains of many families within this order.

### Definition/Identity

The term “psittacine” is an umbrella term for all birds that form the order Psittaciformes. The name for the order “psittacine” is derived from psittacine or, more correctly, psittacofulvin. This is a red feather pigment unique to parrots worldwide, responsible for the bright red, orange, and yellow colors, and is produced in the parrots’ bodies. Puzzlingly, these unique psittacofulvin pigments occupy an essentially identical red/orange/yellow region of color space as the carotenoid pigments found in the passerines (Passeriformes). Parrots have ample concentrations of carotenoids in their blood to color their feathers (McGraw and Nogare 2005) but still evolved this distinct alternative color palette into the long wavelength regions of color space (Stoddard and Prum 2011). Parrots from any group use the same set of five lipochromes to color their feathers in reds (McGraw and Nogare 2005). They can also produce yellow that can fluoresce under UV light.

Feathers with high levels of psittacofulvin are said to resist feather-degrading bacilli. Indeed, in certain species, plumage patch sizes have been linked to health and positive social attributes, but such studies have usually been confined to males. Many psittacines, especially cockatoos, exhibit little or no sexual dimorphism in the visual spectrum, while other parrots are vividly colored, and some are multicolored. Notable in parrots is the lack of sexual dimorphism in plumage. Many are monomorphic, i.e., males and females have the same or very similar plumage. The eclectus parrot, *Eclectus roratus*, shows among the most extreme sexual dimorphism in males, and there is a reversal of the more common dimorphism in male/female coloration: the male has plain green plumage, and the eclectus female has stunning and conspicuous reds and blue.

### Physical Features and Habits of Relevance to Cognition

The finding that parrots, especially macaws (South America/Neotropical), cockatoos (Australia/Oceania), and keas (New Zealand), have extra-large brains relative to body size is now an established fact. Some corvids, often hailed as the “most intelligent birds worldwide,” are just on par with these psittacine species. These factors are based on a raft of biological adaptations to specific and demanding environments.

Although there are substantial size differences between species and families, there are physical commonalities. Even for the least uninitiated in bird identification, it is easy to identify a parrot as distinct from songbirds, fowl, or waterbirds, and this is due to the hooked beak (Fig. 2). One hastens to add that especially the similarities in the feeding apparatus among parrots are usually the result of convergent evolution. They have evolved in unrelated species as adaptations to particular environmental demands (Homberger 1980). The beak is the tool with which parrots and cockatoos can rip, turn, chew, bite, and excavate. Many of the psittacines use their feet for grasping, manipulating, or holding of food.

The beak’s upper mandible (maxilla) is curved and extends over the lower mandible. Its design is thought to point to a common ancestor adapted for forest living. The shape of the beak is already well pronounced in hatchlings (Fig. 3).

**Psittacine Cognition, Fig. 2** The psittacine beak

The largest psittacines, such as macaws and the large cockatoos, have very robust heads with high and massive beaks, while some species, such as the South American slender-billed parakeet, *Enicognathus leptorhynchus*; the Australian long-billed corella, *Cacatua tenuirostris*; and New Zealand's keas, *Nestor notabilis*, have long and slender beaks, suggesting that they can use the

upper mandible as an excavation or ripping tool (Fig. 4).

Psittacines are exceptional for their high levels of exploratory behavior and manipulatory abilities. These manipulative abilities are made possible by distinctive morphological adaptations of the feet, bill, and tongue. The zygodactyl feet of psittacines are distinct from the anisodactyl feet of songbirds (see ► “[Passerine Cognition](#)” entry) in that the second and third toes point forward and oppose the first and fourth toes which point caudally. Such feet are not only useful for a firm grip during roosting. In parrots, the feet are used for grasping and manipulating items.

Beak shape, tongue morphology, musculature of the tongue and jaw apparatus, and skull morphology have been the subject of many investigations because by doing so one can study feeding adaptations as well as vocal performance and signal diversity. The upper jaw and skull evolution in parrots and cockatoos are quite complex (Homberger 1980, Bright et al. 2019). The bill tip organ further provides tactile information and acts like an additional mechanism to assess the quality of food or the nature of objects (Demery et al. 2011).

The tongue of parrots is also unique to parrots, very fleshy and equipped with an internal bone that gives the tongue maneuverability for manipulating food. But this may not be its only function. The tongue, its extrinsic musculature, and the hyoid apparatus generally are referred to as the lingual apparatus, and it has been investigated in

**Psittacine Cognition, Fig. 3** Eastern rosella hatchling 2 days old. (Photo credit: G. Kaplan)

**Psittacine Cognition, Fig. 4** Long upper mandibles (maxilla). Left: Chile's slender-billed parakeet, *Enicognathus leptorhynchus*; right: the Australian long-billed corella, *Cacatua tenuirostris*. In addition to the

specialized beak structures, note that all cockatoos have crests, some far more elaborate and even colorful, used extensively in communication. Insert: New Zealand's kea, *Nestor notabilis*. (Photo credit: G. Kaplan)

detail in African gray parrots, *Psittacus erithacus* (Homberger 1986), and in the orange-winged amazon parrot, *Amazona amazonica* (Nottebohm 1976). Nottebohm (1976) suggested that parrots may use their tongues to modify the shape and thus the resonant properties of the vocal tract. Tongue movements observed in parrot vocalizations independently modulate formant characteristics from the vocal source. This may be an important factor in the production of their natural vocalizations (Beckers et al. 2004) as well as in their remarkable ability to articulate and mimic human words and sounds which they can do with surprising accuracy (see section “Vocal behavior” below).

## Social and Environmental Conditions

For many years, it has been asked what circumstances drove the evolution of this particular order, and of specific families within this order, to evolve into the large-brained and long-lived species as we know them today. Research had uncovered that brain size was related to a confluence of various environmental and social circumstances. Many psittacine species, especially conures, macaws or cockatoos, and also many other parrots, exhibit a high degree of fission-fusion behavior. A fission-fusion society indicates a fluidity of size and composition, i.e., the social group may vary in size and membership throughout a season. Several family groups may merge into one group (fusion) when roosting together or at times of external threats (stationary or in the air), or they may separate (fission) when foraging in small groups during the day or splitting into pairs for exploratory flights or at breeding time. Further, pairs tend to form long-term pair bonds (Kaplan 2019; Torres-Ortiz et al. 2019), and their offspring have substantial adult guidance for periods well exceeding that of most songbirds and other avian species (Kaplan 2019). Apart from developmental and experiential advantages of a slow maturation process, they also have the advantage of being able to socialize with same-age and older members of their species and also unrelated individuals of a larger flock. Further, as

parrots are largely forest species relying on fruits, nuts, and/or seeds, they (a) require a good memory for geographical location of available foods and (b) understand seasonal timetables for foods ready to harvest. Long-distance flying and searching while keeping family members safe and retaining contact with them further require communication often over long distances. It is generally agreed that the foraging habits of parrots are cognitively demanding and given their complex social system (a construct most likely to have evolved because of their foraging habits) in turn suggest the need for a complex communication system (Torres-Ortiz 2019), which in turn may signify social cooperation and supportive traits of sharing knowledge of new food sources.

These social and environmental conditions combined are thought to have primarily contributed to larger brain sizes (Bradbury and Balsby 2016). Subsequently, researchers who wanted to learn more about the cognitive abilities of parrots and cockatoos tended to choose species in which all these characteristics described here are present (long-lived, complex social system; slow maturational development) such as keas, peach- and orange-fronted conures, or Amazons as well as African gray parrots and Goffin cockatoos (see laboratory studies below). Sol and colleagues (2007) concluded in their study on mortality versus brains that the larger the brain, the lower was the mortality rate. Hence, they appeared to have established in their study a clear and identifiable benefit in having a large brain.

## The Psittacine Brain

The reason for a predilection with brain size in relation to cognition was stated bluntly in 2005: “advanced cognition can only occur where there is sufficient neural tissue to perform complex cognitive tasks” (Iwaniuk et al. 2005). Hence, measurements of parrot brains have been extensive. The most common and relatively simple one is to compare relative brain weight with relative body weight. It can reveal unusually large brains compared to the mean of avian species. For instance, the budgerigar is the smallest of all

**Psittacine Cognition, Fig. 5** Mean weight/mass of the brain versus relative body mass in Australian parrots and some cockatoos. The gray line: mean of songbirds; blue, mean of parrots; yellow: mean of cockatoos. The mean of

relative brain versus body size is substantially higher than that of songbirds generally. Species with larger brains within their own group are located above the line (Source: Franklin et al. (2014) and Kaplan (2015))

psittacine species, and the kea is medium size, but the brain size relative to body size of both these species much exceeds the mean of psittacines and is well above the mean for songbirds generally, while the brain of the large eclectus parrot is exceptionally small relative to body size (Franklin et al. 2014).

Among Australian psittacine species, such measures offer a few surprises. Budgerigars (the smallest) and palm cockatoos (the largest) stand out as having exceptionally large brain to body weight ratios, while that of the eclectus parrot is exceptionally small (Fig. 5).

Next came the measurement of the size of the telencephalon (forebrain) against the total brain volume. It generally covaries with the size of the brain, but the percentage of the brain given over to those parts of the brain for cognitive tasks may show variations by as much as ten percent and

even more just within the superfamily of the psittacines.

Measurements of neural density particularly in the forebrain (once called the telencephalon, now the pallium) were also conducted using an isotopic refractometer. The surprising result was that some parrots in similar weight ranges as primates have the same or higher number of neurons (Olkowicz et al. 2016) (Fig. 6 and Table 1).

Gutierrez-Ibanez et al. (2018) argued that evolution of complex cognitive abilities would have required (a) the enlargement of some brain areas and (b) the establishment on additional brain circuits. They found that, indeed, parrots have evolved brain circuits (telencephalic-midbrain-cerebellar circuit) similar to those in primates, which may be of some importance in the way information is processed (Gutierrez-Ibanez et al. 2018).

**Psittacine Cognition, Fig. 6** Position of the eyes. Left: male red-tailed black cockatoo, *Calyptorhynchus banksii* (family: Cacatuidae) – direct upward viewing is blocked by the substantial number of crest feathers, but of course, they can see overhead by tilting the head. Centre: king parrot, *Alisterus scapularis* (family: Psittaculidae) (taken at mid-north coast, NSW, Australia) – very large eyes with clear

views above. King parrots, although quite large, are prey items for most Australian birds of prey. Right: hyacinth macaw, *Anodorhynchus hyacinthinus* (family: Psittacidae) (image taken in the Pantanal, Brazil) – the eyes permit views behind and above, suggesting that, despite their size and beak, they have enemies. (Photo credits: G. Kaplan)

**Psittacine Cognition, Table 1** Body size versus brain mass and brain areas in primates and birds. Extracted from Olkowitz et al. (2016); marked with X: monkeys of similar

body weight and their brain sizes and brain and forebrain neuron numbers compared to parrots/cockatoos of similar weight range

| Species                | Brain mass (g) | Brain neurons ( $\times 10^6$ ) | Pallium neurons ( $\times 10^6$ ) | Body mass (g) |
|------------------------|----------------|---------------------------------|-----------------------------------|---------------|
| Blue+yellow macaw      | 20.7           | 3136                            | 1917                              | 1008          |

### Explanations for Growing a Larger Brain

An argument has been made that climatic variabilities and pressures brought to bear on species by the environment fostered the growth of larger brains. This was confirmed in a study on Neotropical parrots, arguing that differences in relative brain size were particularly tied to an increased dependence on more open and climatically unstable habitats (Schuck-Paim et al. 2008). One would expect that such large-brained species should then tolerate a higher degree of environmental

uncertainty and be more adaptable than species without such adaptations. Yet, about the greatest proportion of species currently on the endangered list are parrots. The latter is not an indication of their inability to adapt (although the time span for such adaptations to human-induced climate change is generally considered far too short in evolutionary terms) but a sign that the human predilection for colorful parrots has encouraged and supported a growing and thriving poaching subculture that continues to this day, plus, of course, ever-accelerating habitat destruction.

Other explanations for evolving large-brained species have been far sparser than descriptions of the consequences of advanced cognitive abilities. Many studies were quick to point out that having a large brain offered many distinct advantages. Relative brain size in birds has been correlated with greater flexibility of behavior, shown in abilities to colonize new areas, including urban environments, and to adjust the time of breeding to a changing climate. Larger-brained species should tolerate a higher degree of environmental uncertainty. Parrots are known for their highly inquisitive nature, sharing this quality with corvids, primates, and some other vertebrates. Many of the features believed to be associated with advanced cognitive processing, such as high levels of sociality and life history traits, are marked by high longevity, slow development, and a long period of parental investment.

## Brain Lateralization

Brain lateralization refers to the specialization of the brain to carry out different types of processing on each side of the brain and hence to control different behavioral responses. To consider the importance of brain lateralization, one first has to consider the visual field of birds and of parrots. In cockatoos and macaws and in most parrots, the eyes are positioned such that their binocular visual field is relatively small while the monocular field is large. This is so because the eyes are placed laterally on each side of the head in such a way that each eye's field of vision faces in a different direction. In other words, most of their visual field is monocular. There are also species differences as to whether the eyes limit overhead vision or whether the above field is visually accessible. Smaller parrots and macaws have eyes set well back on the head to enable overhead vision, while cockatoo species all have crests that may partially or totally block overhead vision (Fig. 6).

Viewing the world monocularly means seeing very different things on the left and on the right side of the head. Moreover, as in all avian species, the information transmitted by the right eye crosses over in the brain to the left side of the

brain and is processed in the left hemisphere. Likewise, information from the left eye crosses over to the right hemisphere and is processed there. Processing information in different brain hemispheres can also mean that each brain hemisphere can become specialized for processing different things (many birds view an object first with one eye and then the other); specialization not only avoids duplications but also enables the brain to perform many different and nuanced tasks and therefore also increase the amount of information and processing (Rogers 2012).

The right hemisphere is responsible for intense emotions (such as fear of attack), and these are largely controlled by the amygdala: a structure just beneath the forebrain. Hence, the right hemisphere expresses intense emotions, and the left hemisphere may inhibit some of these strong responses (Rogers et al. 2013). The right hemisphere is largely responsible for detecting fine details which includes the ability to recognize conspecific individuals, mates, and partners. While the right hemisphere is responsible for strong negative emotions, it also regulates some strong positive emotions and social attachments. Importantly, the right hemisphere responds when there is danger (such as a predator), and it is generally capable of strong and instant action. As in other vertebrates, fear and escape are controlled by the right hemisphere.

The left hemisphere (right eye), by contrast, largely takes care of learned behavior and routine functions. It discriminates between objects (food from nonfood) and processes geographical markers. However, the left hemisphere can only process classes of objects and organisms as categories, and thus, the left hemisphere does not distinguish between individuals or finer points. That is accomplished by the right hemisphere (left eye).

If certain tasks are largely performed by the left hemisphere and others consistently by the right hemisphere, we speak of a lateralized brain, meaning the division of tasks is stable at the population level for that species (Rogers 2012). It can be inferred that the stronger lateralization is, the swifter and more focused the ability to respond (Rogers et al. 2004).

**Psittacine Cognition, Fig. 7** Footedness shown in food manipulation and feeding. From left to right: left-footed sulphur-crested cockatoo, little corella, yellow-tailed black cockatoo, right-footed rainbow lorikeet, and hyacinth macaw

The question arises whether lateralization is of some importance in cognition. This has been tested in parrots by simple behavioral tasks of scoring which foot they use for manipulating food (Fig. 7).

### Footedness

The researchers (Magat and Brown 2009) tested lateralization (and its strength) of foot and eye use and then conducted cognitive tasks (means-end test; see below) to see whether the lateralization index corresponded with cognitive performance levels. They used eight Australian parrot species; first, cockatiels and budgerigars – two Australian species known not to use their feet for feeding and not to have a foot preference on other tasks (i.e., they have no “footedness” but may otherwise be weakly or strongly lateralized) – and, further, six other species that do use their feet. Four of them were cockatoos (galah, gang-gang cockatoo, red-tailed black cockatoo, and sulphur-crested cockatoo), and two were parrots (Australian king parrot and superb parrot). Note that foot preference correlates with eye preference (Brown and Magat 2011). They found in their experiments that performance was better in species with stronger foot preferences. This was true of the results in a food discrimination task: red-tailed and sulphur-crested cockatoos outperformed every other parrot species, followed by galahs, gang-gangs, and cockatiels, and the least well-performing group (budgerigars, the king and superb parrots), among which there were no significant differences, was also the group with the weakest

lateralization. In a cognitive task (means-ends test), budgerigars and cockatiels could not do it all, while the cockatoos outshone all others. The important finding was that the most strongly lateralized, mostly left-footed (Fig. 7) individuals were also the most successful ones in solving the means-end test.

### Studies of Cognition

Much of what we know about parrot cognition stems from captive studies and from birds bred and held in laboratories in Western Europe and also the USA (Auersperg and von Bayern 2019). Except for some keas, very few of the major cognitive studies were conducted in their place of origin (southern hemisphere) but in the northern hemisphere, i.e., under very different climatic and seasonal conditions. Inevitably, research has tended to concentrate on relatively few species. As Cussen recorded in 2017, in 30 years of research effort, 462 unique individual parrots (incl. 28 African grays, 55 orange-winged Amazons, and 128 keas) were used as subjects in cognition research. In most cases, results have been achieved in laboratories that could not be matched by observations in the wild, either because it would be too difficult or because such behavior, for instance, tool using, rarely occurs in wild psittacines (O’Hara et al. 2019) (see details below). As Piaget first described it in children, the world is first understood through their motor abilities such as touch, vision, taste, and movement. Goffin cockatoos (*Cacatua goffiniana*) have been described as a species with pronounced

behavioral plasticity and practical memory and have special characteristics such as intense curiosity, tactile exploration techniques, and persistence: cockatoos explore surrounding objects with their bill, tongue, and feet (Auersperg et al. 2013). Indeed, this characterization of children and Goffin cockatoos might well hold for all psittacines. Intense curiosity can be a dangerous thing in the natural environment, but if they also retain the memory of their exploits, they may turn them into an advantage.

The question is what cognitive abilities parrots have and why they have them. More broadly, what is it that an animal needs to understand (or know) about the world around it so that it can function, and how can it improve its survival chances – is it by adding knowledge (via experience or associative learning) or, if need be, by adding more brain capacity? Some cognitive scientists have argued convincingly that all vertebrates, including birds, need to come with several core knowledge systems as adaptations in order to function at all. These are not abilities that need to be learned but are basic survival necessities involving basic concepts of numeracy, gravity, geometry, and psychology. The debate was very well summarized in a review by Vallortigara et al. (2010). Concepts such as cause and effect in physical tasks, gravity, and visual cognition, including object permanence (explained below), may be part of the core requirements of knowledge.

The now established fact that many psittacines have large brains relative to body size has usually been associated with a “package” of other life history criteria shared also by primates, cetaceans, and corvids. These include traits such as slow development, long period of parental investment as well as high degrees of social interactions (sociality), and natural inquisitiveness. Some have even pointed to the individuality and capriciousness of behavior characteristic of explorative and playful birds that employ their own idiosyncratic methods when manipulating attractive objects (Huber and Gaydon 2006). Remarkably, psittacine species have in common that they are very long-lived by comparison with other birds in similar weight ranges (in the largest parrots ranging from 40 to 100 years), and this life history

criterion has been related to cognition (Wirthlin et al. 2018).

Among standard experimentally tested technical cognitive tasks are the string-pulling task and the trap tube, which are benchmark tests to comparatively study causal understanding in animals (O'Neill et al. 2019), but there are many variations such as opening boxes and inserting sticks, and all of them test some causality in reasoning in order to choose the right action that leads to a desired outcome. Motivation is usually created by providing a favorite piece of food put in a position where it can be accessed only by removing some obstacles (Gajdon et al. 2013). Keas have been tested on similar sets of tasks and, without hesitation, solved the problem on each occasion and also solved the problem of retrieving food from a box with locks and complicated mechanisms, performing just about as well as chimpanzees (Auersperg et al. 2011; Miyata et al. 2011).

### Means-End Tests

A “means-end test” is a general term applied to tests that typically present a problem in the sense that a desired item that is potentially reachable would remain out of reach unless a number of steps are taken to overcome the problem (which may be an obstacle or simply distance). Hence, as Huber and Gajdon defined it, the exercise “involves the deliberate and planned execution of a sequence of steps to achieve a goal.”

### String-Pulling Task

The string-pulling task is a very well-established test and easy to set up (Fig. 8). It can be used in testing individuals (Krashennnikova et al. 2013), but also be set up in ways that can test the willingness of two birds to pull food toward them, if the experimental design demands two birds to overcome the problem.

One can make this test more complicated or even test cooperation between two parties. One interesting study by Pepperberg (2004) showed how even such a simple test can get cognitively complex and go in unexpected directions. For instance, some of the African gray parrots had learned human referential signals such as “come here” and “pick this up” and expected the

**Psittacine Cognition,**

**Fig. 8** String pulling: the kea faces two strings. One end (b) seems closer in distance to the favorite food item (dotted line) and could be chosen intuitively unless the bird assesses the relationship of the string to the favorite food item and then chooses the one to which the favorite food item is attached (a). Most parrots and many songbirds can do this correctly and spontaneously

appropriate action from the human trainer. The parrots that had not learned the human commands solved the problem of string pulling very quickly by themselves, while those who knew the commands called impatiently to their human trainer and tried to manipulate the trainer with words like “pick it up” and then behaving badly when the trainer did not respond (Pepperberg 2004).

Schuck-Paim and colleagues (2009) offered an interesting hypothesis. They proposed that problem-solving ability (as the means-end test represents) is related to social complexity. In order to prove their idea, they selected species with varying degrees of social complexity (i.e., specific traits of social organization). The first two they chose were highly social, living in large fluid groups, as is true of the South American spectacled parrotlet, *Forpus conspicillatus*, and of the Australian galah, *Cacatua roseicapilla* (more below). As the second variant, they chose the Australian rainbow lorikeet, *Trichoglossus moluccanus*, which also lives in highly social and fluid groups but without a crèche system. Finally, they selected two species characterized by small and stable group composition with one stable (dominant) breeding pair: the South American green-winged macaw, *Ara chloropterus*, and the Australian sulfur-crested cockatoo, *Cacatua galerita*.

The researchers then presented all four species with the same experimental design, asking of them not simply to do an individual means-ends test but to do so via observation, designating an observer and a demonstrator. Their hypothesis was confirmed: the parrotlets performed best, followed by the rainbow lorikeets, both of which followed exactly what the demonstrator had done, while the macaw and the cockatoo made more errors. In other words, the more complex the social system, the more likely it was that the bird could solve the problems and learn from demonstrators (Schuck-Paim et al. 2013).

**Trap-Tube Task**

The trap tube is one of the benchmark tests to comparatively study causal understanding, in this case, grasping physical causality (gravity), in animals (O'Neill et al. 2019). The task demands manipulating a food item past a trap (Fig. 9). Noticeably, parrots do not perform well in this test, including keas and cockatoos, while apes and corvids succeed (Liedtke et al. 2011). As we already know, cockatoos and keas are masters in dissecting and solving complex problems, so their poor performance raises many questions, one of them on experimental design. Parrots are usually not nest builders, except for the ground parrot, and thus do not routinely manipulate sticks. Many of them, as was already shown, use their feet for

**Psittacine Cognition, Fig. 9** Variants of the trap-tube task. Food item: gray. (a) Pushing a stick would result in losing the treat into a trap; hence, the stick has to be removed and inserted on the other side. (b) Two downward traps but one of them is open and releases the treat. (c) Downward trap tubes but one of them is closed off at the top. Each task, while similar, requires an examination of where the treat might drop into something irretrievable

manipulation and ought to have been given alternative ways (via the feet) to retrieve the food (Fig. 9).

Hence, one cannot tell from the results of such a test whether the failed outcome was the result of physical limitation rather than a lack of understanding of the problem. In the very least, the results should caution us to rethink what we term tests of cognition (or intelligence).

### Object Permanence

The concept of object permanence plays a significant role in the theory of cognitive development in children, first developed by psychologist Jean Piaget and later adapted as an important concept in animal behavior. According to Piaget, there are four stages of cognitive development in children. Object permanence belongs to the first stage. Briefly, it means that the individual needs to know or

learn that things continue to exist even though they go out of sight and cannot be seen.

Object permanence has been tested in many birds be they songbirds, non-songbirds, or parrots. African gray parrots, as well as budgerigars and Australian cockatiels, have also been tested on various tasks relating to object permanence. On a number of occasions, they solved the tasks that were assumed to be more difficult before they attended to the easier ones (Pepperberg and Funk 1990). However, the number of bird species tested other than parrots, pigeons, chickens, and corvids remains very small and does not compare to the wealth of papers on the subject in primates. In precocial birds (fully feathered, walking, and self-feeding very soon after hatching), this ability is an essential adaptation, i.e., it is the ability to follow a parent immediately post-hatching even when going out of sight. In altricial species, as all parrots are (helpless, nest-bound, and underdeveloped at hatching), object permanence is an ability that has to be learned, as is also the case in humans.

### Numeracy/Assessing Volumes

Numerosity has been tested a number of times in African gray parrots (Pepperberg 2006). The same abilities have been tested in primates and dolphins (Kilian et al. 2003) but, to my knowledge, not in any other psittacine species. Some birds (chicks and Clark's nutcrackers) have also been tested on ordinal positioning, and it has been found that they can not only order objects from lower to higher but also do so from left to right (Rugani et al. 2010a). This leftward bias assumes that the lower number is on the left side.

African gray parrots have also been asked to select the largest amount of food between two sets, either discrete food items (experiment 1) or as volume of a food substance (experiment 2) (Al Ain et al. 2009). No matter what combinations and conditions the experimenters used (volumes of fluid or seeds), subjects performed above chance for almost all combinations. Accuracy was negatively correlated with the ratio, that is, performance improved with greater differences between amounts.

A more abstract knowledge of volume is provided in experiments requiring insight into the

fact that stones can displace water and make the level of the water rise, finding such solutions to a problem that demands knowledge of physical causation. Experiments have shown that rooks, Eurasian jays, and New Caledonian crows managed to solve Aesop's fable paradigm, using stones to raise a water level to get a previously out of reach reward. When keas were tested by Schwing et al. (2019), however, it seems that they managed to bypass the problem without showing any evidence of understanding the physical causation of water displacement, highlighting either that such an understanding is not required for solving Aesop's fable or that circumventing problems may also be a remarkable cognitive feat.

### Food Searching/Memory

In 2014, Cussen and Mench were among the very few and first researchers that investigated cognitive abilities in a Neotropical parrot species (the orange-winged Amazon parrot, *Amazona amazonica*) by using a food-searching task. The test used was a standardized test, called the Hamilton search task which has been widely used in primates and is considered a cognitively complex task. Their results showed that almost all (92%) of the parrots acquired the task and were able to alter their search strategies when reward contingencies changed, demonstrating cognitive flexibility. Their findings also showed that lateralization (of foot use) had a significant influence on learning set acquisition and, just as impressively, the parrots were able to remember the task for 6 months, demonstrating long-term memory. More strongly lateralized parrots performed better on the initial search task, but did not show more cognitive flexibility.

### Inferential Reasoning

Inferential reasoning refers to the ability of an individual organism to infer something from a context. For instance, shake a closed container, and if it rattles, the listener can infer that there is something inside the container and by the type of rattling sound created may even guess at the contents. If it is known that this type of container holds kernels of food and there are two containers and the first one does not make a sound when

shaken, it could be inferred that the food might be in the second container. An experiment with African gray parrots did exactly that using noise created during the shaking of containers to detect hidden food. Even from the very first trial, the parrots inferred correctly that the absence of noise in a shaken container meant that the food must be in the other, non-shaken container (Schloegel et al. 2012). Such immediate understanding has been shown in dogs and great apes, in other birds (pigeons, Clark's nutcrackers, and corvids), and in children from an age of 3 to 4 years (Pepperberg et al. 2013).

### Nonverbal Signals (Gestures, Body Postures, Facial Expressions)

One advantage of living in a social group is having access to information provided by conspecifics, to locate predators and food sources. Social animals can also use social cues provided intentionally or unintentionally. Even nonverbal cues can become meaningful signals that are understood by the entire group. Most parrots have an elaborate system of communicating their state or intention by feathers alone. In cockatoos, the position of the crest can indicate play readiness (fully forward), alarm (half-mast), or anger (erect) and be accompanied by body movements such as head bobbing or wing flapping (play readiness) and arching of the neck (anger) and also by simultaneous vocalizations (for an extensive coverage of these issues, see Kaplan (2015)).

Facial expression is achieved by movements of the beak; by independent positioning of feathers below or above the beak, on the ear coverts, on top of the head (the crown), and at the nape of the neck; and, in some species, also by moving the feathers above or below the eyes independently of other feathers. In recent research, the role of colors in the communication of emotions between birds has led to surprising discoveries. Changes in facial coloration are well-known in the human context (blushing, paling), but this has never been observed until recently. For instance, blue and yellow macaws (*Ara ararauna*) have been found not only to have facial displays but even spontaneous color changes

in their face, both at the bare skin patch (“blushing” turning a hue of pink) and changed feather positions (Bertin et al. 2018). For learning more about social and emotional cognition, it would seem well worth investigating the potential importance of facial expressions in close range communication in birds. Birds also have open mouth displays or, rather, open beak displays, which, together with other body signals, are usually used in fear or threat displays or during hyperventilation.

Eye and head movements can also be informative and shared. A stare in one direction, say down at some branch, and wings extended may alert others that there may be a snake hiding in the foliage. Even if this was an affective and spontaneous act, it will be understood by others who might immediately retreat from the area.

Looking (eye gazing) and pointing may also be intentional, and the direction of eye/head movement and the body may lead others to look in the same direction. Pointing and gazing (human cues) were tested in three African gray parrots in an object-choice task (Giret et al. 2009). They found that one subject spontaneously used the most salient pointing gesture (looking and steady pointing with hand at about 20 cm from the baited box). The two others were also able to use this cue after 15 trials. None of the parrots spontaneously used the steady gaze cues (combined head and eye orientation), but one learned to do so effectively after only 15 trials when the distance between the head and the baited box was about 1 m.

## Play Behavior

Play behavior has rarely been discussed specifically under the rubric of cognition, but latest research has confirmed that playing may be an important variable to consider in cognitive performance. Play behavior tends to be discussed in three distinct categories of play, single (or locomotory) play, object play, and social play, and these categorizations have continued to be applied as meaningful categories in describing structure, and often context, of play behavior (Ortega and Bekoff 1987).

The first category, called solo, solitary, or locomotory play, includes a very wide range of behaviors such as running, skipping, jumping, ducking, rolling, hanging, swinging, dancing, and even sliding and snow romping. In the second category, object play, activities involve objects of any kind ranging from sticks, to stones, to small household objects. Such object play in birds can also lead to social play as a chasing game or even play fighting. The third category is social play and involves the playing together of any two or more individuals. Such interactions have been documented in far fewer species than solo or object play. Published cases of social play so far are largely limited to psittacines and corvids. Social play may include aggressive and play fighting on the ground and in the air (Diamond and Bond 2003; Skeate 1985).

It is clear from the evidence that, at least among Australian psittacine species, there is a powerful association between brain size and play behavior. The largest brains relative to body size belong to species that play socially, but even in species that play non-socially, brain size is larger than that nonplaying species but smaller than that of social players. This was the finding of a research paper that compared brain size with play behavior and also with tool using. The surprising results showed that tool using seemed to count for little in overall brain size while play behavior was significant, positively correlating with brain sizes of any form of active play (Kaplan 2020a), future research might well want to explore the capacity for social play in many psittacine species as a frontier of cognitive research (Pellis and Pellis 2016).

## Cooperation, Prosocial Behavior, and Cognition

Social organization of any species is important, and evidence of results in any vertebrates and even in invertebrates demonstrates convincingly that cooperative behavior in general (not as a specialized behavior as helpers at the nest) can lead to particularly good outcomes. As explained before, many parrots and cockatoos live in fission-

fusion societies, and their main unit of sociality is the long-term pair bond, i.e., they have stable pair units that may last a lifetime but also have associations with other family groups that may be mutually supportive. These arrangements permit two different levels of sociality – the intimate and close coexistence with one partner and offspring and the carefully maintained broader social contacts, very similar to some social arrangements in primates, cetaceans, and elephants (Heaney et al. 2017). Whether these are peach-fronted conures, *Eupsittula aurea* (Torres-Ortiz et al. 2020); keas; galahs or sulphur-crested cockatoos; African gray parrots (Péron et al. 2011); or blue-throated macaws, *Ara glaucogularis* (Tassin de Montaigu et al. 2020) which have all been tested, we find that they not only cooperate well but also can solve problems cooperatively.

Cooperation can occur between individuals of the same and different species. Several studies have examined the intentionality of this behavior and tested the birds' understanding of the need for a partner when working in pairs or even family groups. There is now increasing evidence that cooperation is advantageous to animals, and in some parrot species, it has been shown that cognition is implicated and leads to sharing and cooperation (Schwing et al. 2016).

Kaplan (2020a) argued recently that pairs with juvenile history of bonding will also be likely to form bonds early and be more successful in parenting and in producing surviving offspring. Indeed, a presexual bonding may become a training ground for learning mutual responsiveness between the pair partners even including voluntary sharing and mutual support. The latter is related to qualities such as empathy (as perspective taking) and thus an increasing awareness of interests and needs of others. Guo et al. (2019) argued that the higher the cognitive ability, the more likely is the expression of prosocial behavior. It seems that some species are other-directed, and that is often expressed in their social system. The social organization of galahs, *Cacatua roseicapilla*, may serve as an example here. Galahs hatch asynchronously and also fledge asynchronously which presents a

problem of location of feeding. Galahs have found an ingenious solution by establishing a crèche in which newly fledged and young juveniles congregate, being supervised by one or two adults while the parents can fly off feeding elsewhere, then feed their nestlings not ready to fledge in the nest hole, and eventually fly back to feed those supervised in the crèche. Such crèche arrangements last for several weeks in which time the youngsters from different families get to know each other and may form close affiliations, i.e., have opportunities to develop prosocial tendencies, and they may also begin playing with each other (Rowley 1980). Teitelbaum et al. (2017) found bonding behavior in a case of totally unrelated order of birds, the migratory whooping cranes, *Grus americana*. They had tagged a multitude of birds before sexual maturity and then analyzed 58 breeding pairs of the ones that had been tagged. Results showed that the majority of the breeding pairs had started associating at least 12 months before first breeding, and some breeding pairs had associated with their future partner for over 2 years before first breeding. These pair bondings happened before either one of the future partners had reached sexual maturity. Having such data in hand makes it all the more plausible to hypothesize that species, such as parrots, known to be gregarious, large-brained, and capable of long-term bonding, have the social and cognitive prerequisites for empathy and many of the qualities, such as patience, self-control, and perspective taking. In research on humans, it has been asked and apparently confirmed that smarter individuals are also more prosocial and more attuned to the possibilities of cooperation (Guo et al. 2019). There are many open questions that have only begun to be raised in the late 2010s and are just beginning to be addressed.

## Vocal Behavior

### General Calls

Psittacines, even though they are not songbirds, are vocal learners, and thus, their cerebral architecture includes unique vocal and auditory nuclei,

which are not present in non-songbirds. More importantly, the psittacines share a capacity for open-ended learning, meaning that they can learn new sounds throughout life, an ability that not all songbirds possess (they may have a sensitive period in which they can learn and then their song or songs crystallize and take on the final form) (see ► [“Passerine Vocal Communication”](#)). Usually, parrot communication has been described as complex although this requires further clarification. In Neotropical and New Zealand parrots, in which vocal repertoire in the wild has so far been described, the repertoire varies between five and ten major call types for long and mid-distances and some short-range calls, such as sentinel call, flight contact call, and feeding appeal. In close encounter, some species may use gestural communication and low-intensity calls (Martins and de Araújo 2020).

All of these factors combined generally suggest that such call types, when mixed and matched according to context, may add up to substantial vocal complexity, and such complexity, largely speculative so far, may reflect high cognitive capacity (Martins and de Araújo 2020).

### Recognition Calls

Some calls need to be learned and remembered by newly hatched nestlings. Galah parents, for instance, devote considerable time in getting their youngsters to be vocally responsive. They simply do not feed their young until the young emits a special vocal signal first, training them to do so and making them listen to their parents' low-intensity calls (Rowley 1980). The reasons for such detailed preparation become obvious when the social context of their crèche system is considered containing a small or large number of newly fledged or older fledglings looking very similar to each other. As also in colonially nesting species, making sure that one picks up one's own offspring is achieved by voice check. It is so personal and so specific that, even in large and noisy groups, parents and offspring successfully recognize each other, but unlike shore bird and colonial nesters, in galahs, such recognition needs to be learnt.

### Referential Signals

Meaningful communication, as we understand language in human terms, can also be found in signals, referred to as “referential signals.” These are vocal signals that impart unambiguous and stable meanings, as has been studied in alarm and food calls in some songbirds (see ► [“Passerine Cognition”](#)). A referential signal has a semantic content rather than being generalist, i.e., a call that indicates a specific item be this a food source to lead the group to that source or contain a warning to conspecifics that a predator is near. It is other-directed and designed to inform others. Since parrots are lifelong learners, they can add new words or sounds throughout life, and those species with sentinels emit specific calls that inform all others (Martins and de Araújo 2020). Whether or not parrots have specific calls for aerial or terrestrial predators and how widespread this is has as yet to be examined in their natural environment.

### Vocal Mimicry

Vocal mimicry is defined as the imitation by birds of sounds outside their species-characteristic vocalizations. Far from elucidating important links between the ability of vocal learning and cognitive capacity, vocal mimicry has been regarded by some as an impressive motor skill but little else. Mimicry, particularly by various psittacine species, such as budgerigars, cockatiels, galahs, corellas, and sulfur-crested cockatoos, has been discredited as an artifact of captivity and hence as being of no further scientific interest.

However, there are several contexts and circumstances in which mimicry is part of a fundamental process of survival. For instance, birds may mimic (or copy) their own parents or members of their group. Such copying and being absolutely accurate about a specific sound profile are important for individual or group recognition and can facilitate and enhance communication within groups (Wheatcroft and Price 2013). In addition, birds may copy sounds of neighbors of the same species often as a concession to peaceful coexistence between same-species neighbors and closely related species. Full mimicry from other

species may be in snippets or segments or contain copies of key sounds of mammals (or the sounds of inanimate objects). In captivity, parrots mimic human speech, sometimes whole sentences, and, as one cockatiel in our neighborhood annoyingly did most of the day, were to have copied the sound of a phone ringing so accurately and loudly (the old-type landline phone ringing) that the neighborhood kept running to check their own phones.

Vocal mimicry has generally been considered marginal to science in that it seemed to have no particular function. But do birds merely “parrot,” and is it just an artifact of captivity? Irene Pepperberg tried to convince us otherwise by engaging in meaningful vocal exchanges with her African gray parrot, Alex (Pepperberg 2007). And indeed, vocal imitation cannot be so easily dismissed, because it is a widespread behavior, especially so in Australian birds. Vocal mimicry is a rather special ability performed by psittacine species, songbirds, cetaceans, some seals, and humans (Moore 1996).

Parrots, particularly birds growing up in captivity, usually have a focal human partner and learn to adopt parts of their language, just as they may initially mimic their own parents. Mimicry may thus not just be mindless copying but, in some important instances, need to be regarded as a first stage in vocal learning. As experiments with Alex, the African gray parrot, have shown, there was evidence that the sounds he uttered had outgrown mimicry because the words were now applied in new but correct contexts (Pepperberg 2007), i.e., the bird had learned and understood their meaning and used them only in contexts in which they were meaningful. This is indeed evidence of cognitive capabilities for meaningful communication.

In summary, the extent of cognitive abilities in psittacine species has been thoroughly investigated but has been undertaken in very few species. Still, this research has so far revealed remarkable abilities, but whether these observations hold for the vast majority of psittacine species that have not been tested is not clear. One would expect substantial variations in specific abilities in different species and in accordance with taxonomic relationships. The evolution of extra-large-

brained cockatoos, macaws, and keas cannot be truly understood until we begin to understand the mechanisms and specific relationships of psittacine birds among each other and in their specific environments. Given the extraordinary abilities that have already been discovered, this will be a fertile field for future research.

### **Definition**

The psychopharmacology of sex steroids is the study of how sex steroids, which are cholesterol-derived lipid hormones produced by the testes and ovaries (the gonads), affect mind and behavior.

### **Introduction**

Gonadal steroids – also known as sex steroids or gonadocorticoids – are powerful hormones that are released by the gonads and travel in the bloodstream to reach target receptors (Balthazart et al. 2018). Activation of steroid receptors induces numerous biological and behavioral responses. The primary sex or gonadal steroid families are

androgens (19 carbons), estrogens (18 carbons), and progestagens (21 carbons) (Kamrath et al. 2014). In humans, the most active forms from each family are testosterone, estradiol, and progesterone, respectively. The largest producer of sex steroids are the reproductive organs, i.e., the testes and ovaries. The brain and adrenal glands can also produce these hormones, occasionally contributing to disease states (Turcu and Auchus 2015). Because of their lipid nature, sex steroids easily diffuse across the blood-brain barrier to reach their target cells in the brain to alter behavior. Steroids can act by binding to receptors found in the cytosol, in the nucleus or on the plasma membrane. Steroids have been shown to have long-lasting effects through actions on the genome that regulate the production of peptides and proteins to affect cell structure and function.

Gonadal steroids have been implicated in many different behaviors including aggressive behavior, sexual behavior, depression, and parenting. Their role in behavior was first described in 1889, by Charles Brown-Séquard, who injected himself with fluids extracted from the testicles of animals and experienced a number of astonishing health improvements including a pronounced increase in physical strength and mental stamina (Brown-Séquard 1889). His publication created international interest and by the end of the year over 12,000 physicians had prescribed the “Elixir of Life” for a variety of conditions including epilepsy and hysteria. Most of these treatments had no scientific merit and little if any effects on patients.

### **The Hypothalamic Pituitary Gonadal Axis (HPG)**

The production and release of gonadal steroids is regulated by the hypothalamic – pituitary- gonadal axis. This group of glands is connected by feedforward and feedback loops that assure steroid production within a functional range (Fink et al. 1991).

The hypothalamus is a region in the brain that sits just above the optic chiasm and regulates a

wide variety of functions including, aggression, circadian rhythms, drinking, feeding, parenting, temperature, and mating. The hypothalamus communicates with the pituitary gland by releasing chemical (anterior pituitary) and neural (posterior pituitary) signals.

The pituitary is actually two glands. The anterior pituitary is a group of cells that release hormones when stimulated by releasing factors or hormones produced by the hypothalamus. Releasing hormones are produced in neurons, and then released into the portal veins that surround the hypothalamus and anterior pituitary. Releasing hormones bind to receptors on “trophs” or cells that produce “trophins” or hormones that travel through the bloodstream to their receptors on target organs. The target organs, in turn, release hormones that travel through the bloodstream to affect the brain and body. In contrast to the anterior pituitary, the posterior pituitary is actually a neural structure – it contains nerve endings and axons of neurons whose cell bodies lie in the hypothalamus and produce vasopressin and oxytocin.

The hypothalamic pituitary-gonadal-axis has the following components. The hypothalamus produces Gonadotropin Releasing Hormone (GnRH) which stimulates the gonadotrophs in the anterior pituitary to release Luteinizing Hormone (LH) and Follicle Stimulating Hormone (FSH). More recently, gonadotropin inhibitory hormone (GnIH) – a peptide that inhibits gonadotropin release – has been identified (Bédécarrats 2015). In females, LH and FSH stimulate the ovaries to produce estradiol and progesterone. In males, LH stimulates the testes to produce testosterone whereas FSH supports spermatogenesis (the production and maturation of spermatozoa). Testosterone and estrogen feed back on the hypothalamus and pituitary to inhibit the release of GnRH, LH, and FSH. It should be noted that all of the hormones in the HPG are released in a pulsatile manner which is important for normal function. Many receptors “downregulate.” That is – the number of receptors available to accept a hormone decreases after exposure to the hormone. The phasic release of hormones allows the number of receptors to return to previous level (and the organ

or cell to the initial responsiveness) before the next wave of hormone is released (Constantin 2017).

## Steroid Synthesis

The gonadal steroids are synthesized from cholesterol. In humans, the rate-limiting step in creating gonadal steroids is the conversion of cholesterol to pregnenolone within the mitochondria. While steroids are mainly produced in the gonads (the ovary and testis), gonadal steroids are also produced by the adrenal cortex and synthesized by neurons in the brain in mammals and birds. Steroids are lipophilic and hydrophobic – they do not dissolve well in water. They are carried through the bloodstream by globulins such as sex hormone-binding globulin.

## Brain Areas

The key brain regions involved steroid regulation of behavior include the amygdaloid nuclei, preoptic area/hypothalamus, and periaqueductal gray (PAG) (Sokolowski and Corbin 2012).

The amygdaloid nuclei – primarily the medial and cortical nuclei and the bed nucleus of the stria terminalis – receive and integrate signals from each of the senses and many of the internal organs. These nuclei play important roles in behavior by providing salience or emotional content to the information received. The amygdaloid complex then relays this information to the preoptic area and hypothalamus, which play critical roles in the expression of motivated behaviors.

Several nuclei in the preoptic area and hypothalamus have been identified for their roles in specific behaviors (Chen and Hong 2018). For example, the destruction of the medial preoptic area disrupts male mating and parenting while those of the ventromedial hypothalamic nucleus (VMN) disrupt female sexual behavior. Aggression is regulated by the lateral preoptic area. Interestingly, recent studies using optogenetic techniques suggest additional roles for the VMN in male mating and aggression.

The PAG, a large region in the center of the brainstem, receives information from the hypothalamic and preoptic nuclei and projects to motor regions in the spinal cord to effect synchronized movements required for each behavior. The PAG controls respiration and heart rate and has been implicated in the expression of fear and anxiety. Moreover, the PAG projects to the frontal cortex and the accumbens areas involved in decision-making and reward, respectively. Taken together, the connections of the PAG suggest it adds emotional valence to reflexive behaviors (Motta et al. 2017).

## Aggressive Behavior

In humans, aggressive behavior has been studied in relation to sports competition, criminal violence in prison inmates, self-reporting of aggressive behavior after anabolic steroid use, and in laboratory tests of aggressive behavior. Overall, it remains controversial whether or not steroids, mainly androgens, play a role in human aggression.

In nonhuman animals, there is direct experimental evidence that in some species, androgens, and possibly estrogens (which are synthesized from androgens), play a role in mediating aggressive behavior in males. In females, the number of studies studying the role of steroids on aggressive behavior is limited. Aggressive behavior can be subdivided into several categories that include but are not limited to territorial, maternal, fear-induced, predatory, parental, and self-defense.

### Territorial Aggression

Aggression related to territorial encounters has been extensively examined in non-human animals. Evidence suggests that androgens, estrogens, and progesterone play a role in mediating aggressive behavior in some species. The role of steroids is usually species specific, sex-dependent, and seasonally dependent (breeding vs. nonbreeding seasons).

### Maternal Aggression

In some rodent species, the increase in progesterone is correlated with maternal aggression. Non-sex steroids such as oxytocin, and its receptor, are

known to affect maternal behavior in rodents. The hormonal basis of maternal aggression in humans is not well-studied.

## Sexual Behavior

Gonadal steroids play an essential role in the expression of sexual behavior in mammals. Removal of the gonads which produce the steroids reduces or eliminates mating in males and females and treatment with gonadal steroids restores sexual behavior in both sexes. Sex steroids play gender-specific roles. Systemic treatment with testosterone restores male sexual behavior in castrated males by activating neural areas required for copulation and the musculature required for penile reflexes. Testosterone is readily metabolized to estrogen and treatment with estrogen is sufficient to restore many aspects of mating behavior in male rodents primarily through actions on the brain. Estrogen fails to restore penile reflexes; androgens, which regulate the peripheral structures in males, are required for the full expression of the behavior.

Circulating estrogen and progesterone are required for female sexual behavior. These steroids also act on the brain. Estrogen induces the expression of progesterone receptors, thus estrogen treatment must precede that of progesterone to induce receptivity in gonadectomized females. Testosterone has been shown to influence female sexual behavior in rodents primarily through its conversion to estrogen. While there has been considerable interest in the role of testosterone in the regulation of female sexual behavior in humans, clinical studies fail to support a role for testosterone or non-aromatizable androgens in the regulation of libido in women.

## Parental Behavior

Steroids are also important in parenting behavior—castrated rodents do not parent. Gonadal steroids play sex-specific roles (Peter 2017). Estrogen is critical for maternal (mother) bonding after parturition and may work by increasing levels of

oxytocin and its receptors in the brain. Estrogen's role in paternal (father) behavior is still under investigation. Testosterone has been linked to maternal behavior in rodents primarily through its conversion to estradiol. In contrast, testosterone levels are inversely associated with parenting in males. Lower levels of testosterone are found in high caring primate fathers and mothers (including humans) than their counterparts. Interestingly corticosterone, an adrenal steroid, has been shown to be positively related to maternal and paternal responsiveness and can facilitate parental behavior in inexperienced animals. Progesterone levels have been both positively and negatively associated with parental behavior depending on the species and the method of measurement.

## Other Behaviors

### Depression

Testosterone has been shown to improve depressive symptoms in both men and women (Akerman et al. 2017). While the neural basis for this is poorly understood, it may be mediated by receptors for both androgens and estrogens which are high in the "emotional brain" including the amygdala and BST.

### Alcohol Consumption

Gonadal steroids are positively correlated with alcohol consumption. Surprisingly, this effect is sex specific. High levels of testosterone are associated with increased alcohol consumption in men but not women whereas high levels of estrogen are associated with alcohol consumption in women but not in men (Erol et al. 2017).

### Sleep

The quality of sleep differs in men and women (Lord et al. 2014). While women report poorer quality of sleep than men, objective sleep measures suggest the opposite. The quality of sleep differs over the menstrual cycle and is disrupted during periods of hormonal functions such as puberty, pregnancy, and menopause. Nonetheless, hormone replacement therapy is associated with

more restful sleep states. As men age, circulating levels of testosterone decrease and so does the quality of their sleep suggesting a positive effect of androgens on sleep in males. Thus as in other behaviors, the effects of steroids are sex specific.

## Conclusion

Gonadal steroids have profound effects on a number of behaviors. The nature of these effects is tempered by gender and the nature of the steroid. Steroid actions are long lasting, and long-term treatment can have cumulative effects on behavior. To date, much of the work has been conducted on a variety of animal models. To draw proper conclusions, we must continue to find ways to extend this work to humans.

## Definition

The condition of being or the period of becoming first capable of reproducing sexually that is brought on by the production of sex hormones and the maturing of the reproductive organs (such as the testes and ovaries), development of secondary sex characteristics (such as male facial hair growth and female breast development), and in humans and the higher primates by the first occurrence of menstruation in the female.

## Some Definitions Related to Puberty

**Adrenarche** which is the activation of the adrenal cortex to produce adrenal androgens (typically occurs before the onset of puberty)

**Gonadarche** mainly involves activation of the gonads by the pituitary hormones follicle-

stimulating hormone (FSH) and luteinizing hormone (LH)

**Pubarche** is the first appearance of pubic hair

**Thelarche** is defined by the appearance of breast tissue

**Menarche** defines the age of onset of the first menstrual period

**Spermarche** is the first ejaculation (heralded by nocturnal sperm emissions and appearance of sperm in the urine)

## Introduction

Adolescence is increasingly recognized as a critical period in the life course, a time when rapid development of the brain, body, and behaviors opens a window of opportunity for interventions that may affect health throughout life. Puberty results in very rapid somatic growth, brain development, sexual maturation, and attainment of reproductive capacity. It is accompanied by final maturation of multiple organ systems and major changes in the central nervous system and in psychosocial behavior (Patton and Viner 2007). The discovery of continued brain development through adolescence is one of the great advances of neuroscience in the past 20 years. A dramatic spurt in brain development begins during adolescence and continues until the mid-20s, with marked development of both cortical and subcortical structures (Goddings et al. 2012).

## Physiology of Puberty

There have been remarkable advances in the field of neuroendocrinology to understand the basics of pubertal development during the last few decades. The major areas of focus in this discussion are summarized below.

### Pulsatile Secretion and Release of Gonadotropin

The main reason behind the pulsatile secretion of gonadotropins is due to the pulsatile stimulation of pituitary gonadotrophs by hypothalamic gonadotropin-releasing hormone (GnRH). The

background of pulsatile secretion was experimentally proved by some scientists working on immortalized hypothalamic cells *in vitro* to occur much faster than those of GnRH release *in vivo*, suggesting that the central nervous system influences the rhythmicity of such release patterns. The pulsatile release of GnRH and gonadotrope stimulation is particularly important physiologically. The reason lies in the fact that when the pulsatile release is altered to continuous exposure to GnRH, the receptors for GnRH decrease and ultimately produce a post-receptor defect (Fig. 1).

### Negative Feedback

There are evidences that show that children with normal reproductive organs express increased gonadotrophic secretion during the first few years after their birth; however, it is followed by a period of quiescence, which is also commonly called as juvenile pause, and then finally characteristic display of puberty occurs where there is increased gonadotrophic secretion. Subjects with Turner's syndrome, classical example of patients without gonads, have increased gonadotropin secretions even without the development of secondary sexual characters mainly because of non-functional gonadal system. Thus, juvenile pause is necessary for proper timely occurrence of puberty in early childhood displaying a negative feedback control by sex steroids.

### Control by Higher Centers

The major inhibitory mechanism of the central nervous system (CNS) demonstrated by juvenile pause lasts mainly from the age of 1–4 years up to 10–12 years in the maximum number of children, resulting in low or decreased gonadotrophic secretion. The exact mechanism by which CNS exerts its effect is poorly understood; however, certain disorders like Turner's syndrome explain the plausible role.

### Stages of Puberty

Professor James M. Tanner, a child development expert, was the first to identify the visible stages of puberty. At present, these stages are known as the Tanner stages or, more appropriately, sexual maturity ratings. They serve as a general guide

**Puberty, Fig. 1** Activation of hypothalamo-pituitary gonadal axis. Figure taken from Rosenfield R. *Pediatric Endocrinology*. Sperling 3rd edition, 2008

to physical development, although each person has a different puberty timetable.

### Pubertal Stages (Tanner) in Females

The five stages of breast development in females are as follows:

P1: Prepubertal

P2: Early development of subareolar breast bud +/- small amounts of pubic hair and axillary hair

P3: Increase in size of palpable breast tissue and areolae, increased amount of dark pubic hair and of axillary hair

P4: Further increase in breast size and areolae that protrude above breast level adult pubic hair

P5: Adult stage, pubic hair with extension to upper thigh (Fig. 2)

### Uterine Development

The prepubertal uterus is tear-drop shaped, with the neck and isthmus accounting for up to two-thirds of the uterine volume; then, with the production of estrogens, it becomes pear shaped, with the uterine body increasing in length and thickness proportionately more than the cervix (Fig. 2).

### Ovarian Development: Stage 1

The rising levels of plasma gonadotropins stimulate the ovary to produce increasing amounts of

estradiol. Estradiol is responsible for the development of secondary sexual characteristics, that is, growth and development of the breasts and reproductive organs, fat redistribution (hips, breasts), and bone maturation. The maturation of the ovary at adolescence correlates well with estradiol secretion and the stages of puberty.

### Ovarian Development: Stage 2

In prepuberty, the ovarian size volume extends from 0.3 to 0.9 cm<sup>3</sup>. More than 1.0 cm<sup>3</sup> indicates that puberty has begun. During puberty, the ovarian size increases rapidly to a mean postpubertal volume of 4.0 cm<sup>3</sup> (1.8–5.3 cm<sup>3</sup>).

### Ovulation

Plasma testosterone levels also increase at puberty although not as markedly as in males. Plasma progesterone remains at low levels even if secondary sexual characteristics have appeared. A rise in progesterone after menarche is, in general, indicative that ovulation has occurred. The first ovulation does not take place until 6–9 months after menarche because the positive feedback mechanism of estrogen is not developed (Chakraborty 2019).

### Female Secondary Sexual Characteristics

If breast development, pubic and/or axillary hair, and menses occur earlier than normal variations

**Puberty, Fig. 2**

Different pubertal stages in female. Figure taken from Rosenfield R. Pediatric Endocrinology. Sperling 3rd edition, 2008

from the mean, the terms premature thelarche, pubarche and/or adrenarche, and menarche are used.

**Pubertal Stages (Tanner) in Males (Fig. 3)**

- P1: Prepubertal, testicular length less than 2.5 cm  
 P2: Early increase in testicular size, scrotum slightly pigmented, few long and dark pubic hair  
 P3: Testicular length 3.3–4 cm, lengthening of the penis, increase in pubic hair  
 P4: Testicular length 4.1–4.5 cm, increase in length and thickening of the penis, adult amount of pubic hair  
 P5: Testicular length greater than 4.5 cm, full spermatogenesis

**Secondary Sexual Development in Boys**

Growth kinetics are enhanced from early puberty, and maximal velocity is attained only around 14–15 years of age. Testis increases in size, mainly at the expense of the seminiferous tubules, and the interstitial (Leydig) cells develop and ensure synthesis and secretion of testosterone. A testicular volume of 4 ml or a longitudinal diameter greater than or equal to 2.5 cm and a slight progressive increase in scrotal folds and pigmentation constitute the first signs of puberty.

**Testes Development: Stage 1**

The increase in testicular size observed during prepuberty and puberty results essentially from

the development of the seminiferous tubules under the stimulating effect of FSH. The testicular volume increases throughout puberty up to Tanner stage P4 when a longitudinal diameter of  $5.0 \pm 0.5$  cm or a volume of  $17.6 \pm 4.0$  ml is reached.

**Testes Development: Stage 2**

Long-standing pulsatile LH secretion induces the differentiation of interstitial cells into testosterone-secreting Leydig cells, which, in turn, exert a negative feedback control on LH secretion. As puberty progresses, spermatogenesis is initiated and then sustained by FSH and by testosterone produced by the Leydig cells under LH control.

**Testes Development: Stage 3**

A significant increase of plasma testosterone is found only between Tanner pubertal stages P3 and P4. Dihydrotestosterone shows a pattern similar to that of testosterone, and the proportion of dihydrotestosterone to testosterone decreases gradually until adulthood, when dihydrotestosterone levels are approximately 10% of those of testosterone.

**Bone Age**

Puberty is completed usually within 3–4 years of its onset, and the final height resulting from complete fusion of the epiphyses occurs within approximately 2 years after menarche.

**Puberty, Fig. 3** Different pubertal stages in male. Figure taken from Sizonenko 1987

### Precocious/Delayed Puberty

Puberty is considered precocious if these changes are noted prior to 8 years of age in girls and 9 years of age in boys and is considered delayed when such changes do not occur prior to 13 years of age in girls and 14 years of age in boys (Europe).

### Hormonal Changes in Puberty

**Gonadotropin-Releasing Hormone 1:** In prepubertal children, no significant luteinizing hormone (LH) or follicle-stimulating hormone (FSH) response to intravenous or subcutaneous administration of GnRH is observed. During adolescence, the LH response to GnRH increases progressively in both sexes. The increase of FSH is much less marked than that of LH. The primary triggering mechanism that initiates the activation of the hypothalamic-pituitary-gonadal axis at puberty is still hypothetical.

**Gonadotropin-Releasing Hormone 2:** One of the important neuroendocrine mechanisms that control the onset of puberty is probably an increase in the frequency of GnRH pulse stimulation of the pituitary. Whatever the mechanism, the process is not abrupt but develops over several years, as evidenced by slowly rising plasma

concentrations of the gonadotropins and testosterone or estrogens.

**Gonadotropin-Releasing Hormone 3:** One of the factors involved in triggering GnRH secretion is the GPR54 gene, encoding a G protein-coupled receptor. Human mutations of this gene are found in hypogonadotropic hypogonadism. Defect in migration and/or final differentiation of the neurons is found in the hypothalamus. They modulate the activity of GnRH in various ways, leading to appropriate timely occurrence of GnRH release during puberty. GPR54 also regulates the release of GnRH at hypothalamic level.

**Gonadotropins 1:** The first demonstrable biological change of puberty is the appearance of pulsatile LH release during sleep. As puberty progresses, the frequency and amplitude of LH secretory peaks increase, although peaks are also found during the wake period. At the end of puberty, the difference between sleep and wake LH secretory patterns disappears.

**Gonadotropins 2:** In girls, circulating FSH levels increase progressively from 10 to 11 years of age (stage P2), approximately 1 year prior to those of LH. Thereafter, gonadotropins continue

to increase throughout puberty, but important fluctuations are observed in relation to the menstrual cycle.

*Gonadotropins 3:* In boys, a significant increase in both plasma FSH and LH is also found from the onset of puberty (stage P2), closely linked to the rapid increase in testicular size characteristic of this pubertal stage. A further significant increase in circulating gonadotropins is also observed at late puberty (stages P4 and P5).

*Adrenal Steroids 1:* Adrenal androgens vary from infancy through adolescence. This phenomenon is called adrenarche. In girls, dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHEAS) increase as early as 6–7 years of age, followed within 1–2 years by a concomitant increase in androstenedione.

*Adrenal Steroids 2:* In boys, DHEA and DHEAS increase as early as 8–9 years of age, followed by androstenedione 1–2 years later. Adrenarche begins before the rise in gonadotropin secretion. The adrenal androgens are responsible for the appearance of axillary hair and, in part, for the appearance of pubic hair in the adolescent; however, they do not appear to play a decisive role in determining the initiation of puberty.

*GH, IGF-I, and Insulin in Puberty:* There is accumulating evidence that GH plays a role in pubertal development. In experimental animals, GH seems to stimulate FSH-induced differentiation of granulosa cells directly, increase ovarian levels of IGF-I, and amplify the ovarian response to gonadotropins.

IGF-I, in turn, enhances the gonadotropin effect on the granulosa cell, and GH seems to act synergistically with a still-developing pattern of gonadotropin secretion to facilitate ovarian maturation postmenarche. It also appears that the local production or accumulation of GH and IGF-I exerts an intraovarian paracrine control on steroidogenesis.

Puberty of patients with isolated GH deficiency is frequently delayed, Leydig cell function is diminished, and the response to chorionic gonadotropins is decreased. GH administration can restore testicular responsiveness to LH and Leydig cell steroidogenesis.

Growth hormone-releasing factor (GRF) levels and GH secretion increase considerably during

puberty, mainly at night. The amplitude of GH peaks increases early in puberty. IGF-I is an important modulator of growth during childhood and adolescence. Adrenal androgens seem to have no physiological role in normal growth. The characteristic pubertal growth spurt results mainly from the synergetic effect of gonadal sex steroids, growth hormone, and IGF-I production, with all showing a significant increase at the time of pubertal growth acceleration.

Insulin is also important for normal growth. Plasma insulin levels increase throughout childhood, but the rise is particularly pronounced during puberty with a strong positive correlation with IGF-I.

*Leptin in Puberty:* Leptin a peptide hormone is very essential for food intake pattern and regulates food intake and energy expenditure at the hypothalamic level (satiety factor). It is expressed predominantly in adipocytes. Leptin is regulated by body weight and nutrition. Recently, it has been found to be involved in the regulation of GnRH secretion. It interacts with insulin, IGF1, GH, and glucocorticoids, thereby playing a vital role in the regulation and occurrence of puberty in both sexes.

*Puberty and Neurosecretions:* Gamma-aminobutyric acid (GABA) neurons inhibit prepubertal GnRH release and secretion. It has been experimentally demonstrated in monkeys that puberty advances by pharmacological blockade of GABA A receptors. GABA inhibits excitatory neuronal systems synaptically connected to GnRH neurons, thereby blocking GnRH secretion and release. Therefore, during puberty, there occurs an active inhibition of GABA neurons, thereby consequential occurrence of puberty.

## Conclusion

The stage of puberty can be challenging for kids and parents. In addition to causing many physical changes, hormones are also causing emotional changes making the person moody or rage. Children's experiencing puberty might feel insecure about their changing body, including their acne. It is particularly important to understand the physiological reasons and deal accordingly.

## Definition

According to the American Psychological Association Dictionary of Psychology, punishment is a noun that refers to (1) a physically or psychologically painful, unwanted, or undesirable event or circumstance imposed as a penalty on an actual or perceived wrongdoer; (2) in operant conditioning, the process in which the relationship, or contingency, between a response and some stimulus or circumstance results in the response becoming less probable. The punishing stimulus is called a punisher.

The characterization of events or circumstances as “physically or psychologically painful” is not useful unless the observational basis for these terms is spelled out. Therefore, the standard and most widespread definition of punishment in the behavior-analytic literature refers only to a response – stimulus change contingency and a resulting reduction in response frequency. Thus, Azrin and Holz (1966) defined punishment as a procedure that results in a decreased frequency of specific responses when these responses have produced certain immediate stimulus changes. Thus, in the same way that reinforcement requires that the response rate is increased or maintained as a result of the response – stimulus-change contingency, punishment requires that the response rate decreases or remains lowered as the result of the response – stimulus-change contingency.

## History

In the vernacular, punishment and reward are closely related terms. Whereas rewards are generally considered as something pleasant, punishment is considered as unpleasant. However, the terms “pleasant” and “unpleasant” are not well defined. The observational basis for characterizing an event as “pleasant” or “unpleasant” for a particular organism is not obvious.

In an early statement of “The Law of Effect,” E. L. Thorndike (1911) wrote that,

Of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur; those which are accompanied or closely followed by discomfort to the animal will, other things being equal, have their connections with that situation weakened, so that, when it recurs, they will be less likely to occur. (p. 244)

As with the term “painful” mentioned above, it is not helpful to define reward as “a satisfying state of affairs,” and punishment as “a discomforting state of affairs,” without clarifying the observational basis for saying that something is satisfying or discomforting, and so on. Thorndike realized this problem and added that,

By a satisfying state of affairs is meant one which the animal does nothing to avoid, often doing such things as attain and preserve it. By discomforting or annoying state of affairs is meant one which the animal commonly avoids and abandons. (p. 245)

When these definitions were put back into the law of effect, however, another problem was soon realized: the law became circular. The concept of “reward” had other problems as well. In colloquial speech, rewards are defined as much by their intended affect as by their actual effects. Thus, people are rewarded, and whether behavior is actually strengthened is secondary. In modern behavior analysis, the term “reward” is abandoned in favor of “reinforcement.” Reinforcement is defined by its effect – in strengthening behavior. There have been a few efforts to abandon the term punishment in a similar way, and to promote the concept of “reduction procedures.” Yet, the concept of punishment has survived in the behavioral literature.

## Two Types of Punishment Procedures

It is common practice to distinguish between two types of punishment procedures as well as two types of reinforcement procedures: In *positive punishment*, as in *positive reinforcement*, the

response-contingent stimulus change consists of the presentation, or the increased intensity, of a stimulus, whereas in *negative punishment*, as in *negative reinforcement*, the response-contingent stimulus change consists of the removal or reduced intensity of a stimulus. The stimuli that are presented or intensified are designated positive (reinforcers or punishers in the respective procedures), and the stimuli that are removed or decreased in intensity are designated negative (reinforcers or punishers in the respective procedures). Sometimes, both positive and negative punishments are involved simultaneously.

## An Alternative Definition of Punishment

In his classic textbook, *Science and Human Behavior*, B. F. Skinner (1953) had suggested a different definition of punishment than the standard one. He concluded that punishment is not simply the opposite of reward, that punishment did not simply subtract responses where reinforcement added them, and therefore,

We must first define punishment without presupposing any effect. [Then,] what course is open to us? The answer is as follows. We first define a positive reinforcer as any stimulus the *presentation* of which strengthens the behavior upon which it is made contingent. We define a negative reinforcer (an aversive stimulus) as any stimulus the *withdrawal* of which strengthens behavior. . . In solving the problem of punishment we simply ask: What is the effect of *withdrawing* a *positive* reinforcer or *presenting* a *negative*? . . . We do not presuppose any effect; we simply raise a question to be answered by appropriate experiments. (pp. 184–185)

Although Skinner doubted a permanent or lasting reduction in response strength as a result of punishment, the immediate effect on response probability was clear enough. He went on to describe three ways in which punishment may work “indirectly.” First, aversive stimuli may function as elicitors of behavior that is incompatible with behavior upon which those aversive stimuli are contingent. Second, behavior that is previously punished may become (or become a source of) conditioned stimuli that evoke behavior

that is incompatible with the punished behavior. Third, certain responses may be reinforced by reducing conditioned aversive stimulation arising from the punished behavior or from associated circumstances. This effect may be most clearly observed when, as a result of punishment, the organism not only does refrain from repeating the punished behavior, but also shows a marked resistance if manually prompted to engage in that behavior.

### Variables that Influence the Effectiveness of Punishment

When we use the standard (Azrin and Holz 1966) definition, punishment always works – because it is defined that way. If we use the alternative definition (Skinner 1953), the question of whether punishment works is more meaningful. However, with either definition a more useful question concerns the extent to which the rate of specific responses will be reduced when specific stimulus changes are contingent upon those responses. Can we formulate some general rules regarding the circumstances under which punishment is most effective? The central variables that influence the effectiveness of punishment procedures have been identified by Azrin and others in basic research since the early 1960s and their findings have been supported by later work in applied behavior analysis (see Lerman and Vorndran 2002). Some of the most important variables are the following:

1. *Immediacy.* Punishment is most effective when administered immediately after the target response.
2. *Intensity.* Punishment is more effective when introduced at high intensity rather than introduced at low intensity and later increased.
3. *Schedule of punishment.* Behavior is more effectively reduced when punishment is administered contingent upon every response rather than intermittently.
4. *Reinforcement of target behavior eliminated or reduced.* Punishment works more effectively when target responses are not simultaneously

reinforced than when reinforcement remains contingent upon those responses.

5. *Reinforcement of alternative behavior.* Punishment reduces the occurrence of target responses most effectively when reinforcers are accessible through alternative responses. Representative cumulative records of responding under no punishment, straight punishment, and punishment combined with alternative reinforcement is shown in Fig. 1. The steeper the record, the higher rate of responding, thus simple punishment was effective in reducing behavior (compared to no punishment), but it was most effective when accompanied by reinforcement of alternative responding.
6. *Minimized motivation for reinforcers that maintain target behavior.* The effectiveness of punishment increases when motivational variables are changed so as to reduce the effectiveness of reinforcers that otherwise maintains the punished behavior.
7. *No pairing of punishment with reinforcement.* Punishment may lose its effect entirely and even begin to have the opposite effect if consistently paired with reinforcement.

**Punishment, Fig. 1** Cumulative response records of the punished responses of human participants under an intermittent reinforcement schedule. The punishment was an annoying buzzing sound that was delivered for each response. (After Azrin, N. H., & Holz, W. C. (1966). Punishment. In W. K. Honig (Ed.), *Operant behavior: areas of research and application* (pp. 213–270). New York: Appleton-Century-Crofts)

## Theories of Punishment

The two definitions of punishment described above largely coincide with two different theories of how punishment works. According to the first theory, reinforcement and punishment are symmetrical processes. Fantino and Logan (1979) suggested that this symmetrical theory was directly inspired by the symmetrical definitions of reinforcement and punishment. Moreover, the theory was also inspired by the fact that when punishment is shown to reduce response rates, observable competing responses are not likely to be reported (Fantino and Logan 1979).

According to the second theory, punishment is not considered as the opposite of reinforcement. An early, clear statement of this view was made by Thorndike (1932) in his revision of “The Law of Effect,” where he wrote that “the wrong tendencies are not reduced in strength one jot or tittle by the punishment.” Additional support for this view came from Skinner’s (1938) early experiments and from Estes (1944). Skinner (1938) punished rats’ lever presses during a limited time period and found that when punishment was terminated, response rates increased, and the total number of responses was not affected by the punishment. Estes (1944) compared the effect of response-dependent and response-independent electric shocks and found that they were equally effective in suppressing responses. The results suggested a two-factor theory of punishment. According to this theory, punishment works by eliciting responses that are incompatible with punished behavior or by generating conditioned aversive stimuli that are terminated by behavior that is incompatible with punished behavior and, hence reinforce such incompatible behavior.

## Commonly Listed Problems with the Use of Punishment

A series of important side effects of punishment are typically listed in textbook chapters. These include the following:

1. Elicitation of challenging emotional behavior.
2. Weakening of other (wanted) behavior in addition to that which is being punished.
3. Avoidance or escape from those who punish.
4. Aggression toward those who punish as well as toward others.
5. Weakening of behavior only in the presence of persons or situations paired with punishment and as long as the procedure is implemented.
6. Reinforcement of punishing behavior whenever punishment works.

## Effects of Negative Punishment on Behavior

The reinforcement of alternative/incompatible responses to the punished one is at the base of negative punishment. In most negative punishment procedures, a positive reinforcer is cancelled or postponed if the target behavior occurs, and reinforcers occur if the behavior is not emitted during a specified time period, or an alternative response is directly reinforced. But even in the absence of explicit alternative reinforcement, some behavior should coincide with reinforcer occurrence, thus setting the occasion for the operation of reinforcement to occur. As can be seen, negative punishment is an alternative way to reduce target behavior, which complements (and perhaps contrasts) the more traditional positive punishment seen in previous sections.

A consequence of weakening behavior through negative punishment instead of positive punishment is the low, or even lack of, negative emotional side effects, as can be seen, for example, by the failure of anxiolytic drugs to increase behavior reduced by negative punishment in contrast to the clear antipunishment effect observed when the behavior has been reduced by means of positive punishment (Pérez-Padilla and Pellón 2007).

There are different ways to implement negative punishment:

1. *Time-out from positive reinforcement* consists of removing the individual from the reinforcing situation for a defined time period contingent upon execution of a target behavior,

thus resulting in the reduction of such behavior. This technique originated in applied behavior analysis and is commonly used by school teachers or parents. In the laboratory, time-out also refers to a time interval during which a behavior is not possible to occur, breaking trains of behaviors by eliminating their stimulus effects or acting as a marker in a series of events.

2. *Differential reinforcement of other behavior*, or *omission training*, is a procedure in which reinforcement occurs if a particular response does not occur for a specified time period, thus decreasing the rate of the target behavior. If some specific other behavior is identified, then the procedure is better named *differential reinforcement of alternative behavior*. This negative punishment procedure combines extinction of a particular target behavior and reinforcement of a competitor one, even if is not explicitly identified.
3. *Response-initiated delays in reinforcement*, based on the knowledge that response rate decreases as the interval between target behavior and reinforcer delivery increases (known as the delay-of-reinforcement gradient), due to the breaking of the response-reinforcer contiguity.

To exemplify how omission training works coupled with response-initiated delays, consider the procedure where an established response by means of reinforcer delivery is now punished by delays to the reinforcer initiated by each of those responses. This is the case of spout-licking when food is intermittently delivered to moderately food-deprived rats, as shown in Fig. 2. Rats developed a fair number of licks per reinforcer delivery during the first experimental phase (identified as Stage A), then behavior was reduced by negative punishment for master rats (filled circles) during Stage B, and when the delay contingency was removed in the final Stage A behavior resumed. In that particular experiment, delays were signaled by houselight off, but they could be unsignaled (similarly effective), and they were resetting (initiated by each response), but they could be non-resetting (just initiated by the first response, normally not as effective).

A similar lick-contingent delay procedure can be used to reduce initial acquisition of behavior, as shown in Fig. 3, in which individual rats submitted to such negative punishment (filled circles) reduced or abolished acquisition of spout-licking behavior depending on the length of the contingent unsignaled delays. When delays were removed during a second experimental phase, licking developed further in most of the master rats. Thus, negative punishment is an effective procedure not only to reduce already acquired behavior but to impede the establishment of new behavior.

## Ethical Punishment and Societal Issues

For punishment to be effective it should be contingent upon behavior, be consistently applied and be sufficiently intense, as seen before, therefore its application in cases of aversive stimulation cast some doubts in terms of its potential side effects, its potential misuse, and the ethical issues related to the application of aversive treatments to change behavior.

The undesirable consequences in the application of positive punishment, along its lack of long-term suppressive effects, led B. F. Skinner to question the application of punishment in favor of reinforcement as the way behavioral interventions should follow. In *Science and Human Behavior*, he wrote:

Severe punishment unquestionably has an immediate effect in reducing a tendency to act in a given way. This result is no doubt responsible for its widespread use. We ‘instinctively’ attack anyone whose behavior displeases us – perhaps not in physical assault, but with criticism, disapproval, blame, or ridicule. Whether or not there is an inherited tendency to do this, the immediate effect of the practice is reinforcing enough to explain its currency. In the long run, however, punishment does not actually eliminate behavior from a repertoire, and its temporary achievement is obtained at tremendous cost in reducing the over-all efficiency and happiness of the group. (p. 190)

Furthermore, in *Beyond Freedom and Dignity* (Skinner 1971, p. 83), he wrote: “A person who has been punished is not thereby simply less

**Punishment, Fig. 2** Daily mean licks per food pellet for individual rats. Stage A: food pellets were delivered at regular 60 s intervals [a fixed time (FT) schedule]. Stage B: FT 60 s, but with each lick made by a master rat initiating a 10-s delay in food delivery, accompanied by blackout. A yoked rat received food at the same time as its master, but no blackout. During final Stage A there were reinstated the original conditions of the experiment. (Reprinted with permission from Pellón, R., & Blackman, D. E. (1987). Punishment of schedule-induced drinking in rats by signaled and unsignaled delays in food presentation. *Journal of the Experimental Analysis of Behavior*, 48(3), 417–434. <https://doi.org/10.1901/jeab.1987.48-417>)

inclined to behave in a given way; at best, he learns how to avoid punishment,” thus emphasizing the role of negative reinforcement to account for the suppressive effect of positive punishment.

Thus, punishment (positive) often does not seem to outcompete reinforcement at a behavioral level, nor does it appear to do so at a neurobiological level. For example, there seems to be a longer-lasting neural activity after reinforcement than after non-reinforcement or punishment

(Histed et al. 2009). Therefore, the use of explicit reinforcement for alternative responses in combination with extinction of target behavior is advised with negative punishment procedures.

Behavioral recommendations for societal applications of punishment should promote a move from positive punishment to negative punishment and reinforcement of alternative behavior as interventions to reduce undesired behavior. Good contexts can be offered by psychiatric

**Punishment, Fig. 3** Daily mean licks per food pellet for individual rats. Food pellets were delivered at regular 60 s intervals [a fixed time (FT) schedule], and during the first experimental phase each lick made by a master rat initiated a 2- or 50-s unsignaled delay in food delivery. Yoked rats received food at the same time as their masters, but there was no contingency imposed on their licking. During the

second phase of the experiment, food was simply delivered according to the FT 60-s schedule to all rats. (Reprinted with permission from Lamas, E., & Pellón, R. (1995). Food-delay duration and the development of schedule-induced polydipsia in rats. *Physiology and Behavior*, 57(6), 1221–1224. [https://doi.org/10.1016/0031-9384\(94\)00371-B](https://doi.org/10.1016/0031-9384(94)00371-B))

settings or prisons. In the latter case, incarceration normally combines positive and negative punishment, and with the efficacy of positive

punishment being questioned (Apel and Diller 2017), there is room to explore a major role of prisons as places for removal of positive

reinforcement for challenging behavior in combination with the opportunity for reinforcement of alternative behaviors.

## Punishment in Other Disciplines

It may be useful to note that certain disciplines have their own definitions of punishment, which may be closer to the vernacular. In criminology, for example, punishment is typically defined by its purposes (to physically prevent the criminal offender from hurting society, to rehabilitate the offender, to deter the offender and others from further crime, and to get retribution). Such definitions do not require that the purpose to reduce the probability of target behavior is met.

## Conclusion

Punishment is an effective procedure to reduce behavior. However, the application of contingent aversive stimuli upon behavior has cast some ethical doubts and many have questioned its net efficacy. The use of alternative negative punishment procedures, which effectively reinforces alternative behavior, provides techniques capable of reducing undesired behavior without the implication that the use of aversive stimulation might have, thus providing a good alternative for parents, teachers, and applicants of behavioral techniques.

## Synonyms

Pedigree mapping; QTL; QTL mapping

## Definition

Quantitative trait locus (QTL) linkage analysis is a statistical tool which is used to correlate the genotype of a polygenic trait using molecular markers at different genomic locations and the complex phenotype that underlie a quantitative variation.

## Introduction

The quantitative genetics is aimed at anatomization of complex traits. There have been several

advancements in this field, e.g., increased availability of molecular markers combined with enhanced statistical analysis has given many new tools to quantitative geneticists. One such tool is to use quantitative trait locus (QTL) detection methods which utilizes phenotypic and molecular marker data collected in designed biparental mapping populations of large size (Boer et al. 2007 ; Bink et al. 2012).

In order to dissect the QTL detection methods, let us first understand what is quantitative trait and what is quantitative trait locus (QTL). A trait that has measurable phenotypic variation due to interaction of multiple genetic and environmental factors is referred to as a quantitative trait. This variation can display discrete values, e.g., neural tube defects (NTD), or can be continuous such as measurement of height, weight, and blood pressure. The QTL is referred as genetic loci, the alleles of which contribute to the phenotypic variation. QTLs represent a fascinating biological phenomenon that is fundamental to our understanding of human phenotypic variation (e.g., height, weight, skin color). They are also responsible for diversity in human disease susceptibility and severity. Quantitative genetics is largely influenced by allelic frequencies and allelic effects.

Mapping genes associated with various traits and diseases has been one of the most important research areas in human genetics. The process of mapping genes has several steps, but the most critical step is the use of statistical methods for

identifying areas of genome where the target genes are likely to lie. These statistical methods can be broadly divided into two categories: linkage methods and association methods. Linkage methods use family data and try to detect cosegregation of traits and shared genetic material within families. Linkage analysis allows mapping of genes, including genes associated with diseases which are detectable as phenotypic traits only. It is based on measuring the frequency with which two genes remain together through meiosis as they are passed from one generation to the next. Genetic linkage analysis utilizes the frequency of recombination to measure how close genetically different loci are to each other.

The resolution of mapping in QTL linkage studies is dependent on the number of meiosis events. Hence, accounting the meiosis events that have occurred in the ancestors of the parents of the mapping population should be beneficial in the detection of QTL and locating these QTL precisely on the genetic map. A Bayesian approach to combine parental identity by descent (PIBD) information into a QTL linkage analysis was proposed in 2012 by Bink and his coworkers. The parental identity by descent (PIBD) information corresponds to the parents of the connected populations that form the analysis dataset. However, it is assumed that this information is in the form of an identity by descent (IBD) matrix which is specific to a particular marker. QTL linkage analysis is based on the principle that genes and markers segregate via chromosome recombination (crossing over) during meiosis (i.e., sexual reproduction), thus allowing their analysis in the progeny (Patterson 1996). Genes or markers that are close together will be transmitted together from parent to progeny more frequently than genes or markers that are located farther apart.

## What Do We Need for QTL Analysis?

For QTL analysis, we need:

1. A large population of individuals that can be scored for variation in phenotype

2. Markers all over the genome to pinpoint QTL location
3. A way for identifying which markers from each parent have been inherited to the progeny
4. Map of the genome

## QTL Mapping

A detailed genome-wide analysis of the link between genotype at different genomic locations and phenotype for a set of quantitative traits with respect to number, genomic positions, effects, and interaction of quantitative trait loci is referred to as QTL mapping (Zeng 2006). With the help of QTL mapping, we can analyze whether phenotypic differences are due to few loci with greater effect or due to many loci, each having some additive effect.

### Analysis of Variance (Crosses 2001)

The simplest method for QTL mapping is analysis of variance at the marker loci (Soller et al. 1976). This method is also known as ANOVA or marker regression. In this method in a backcross, a t-statistics can be applied to compare the averages of the groups of two marker genotypes. In some other types of crosses (e.g., intercrosses), there is a possibility of getting more than two genotypes, in such cases a more general form of ANOVA is used, which provides F-statistics. There are mainly three shortcomings of this mapping method:

1. A separate estimate of QTL location and QTL effect is very hard to obtain.
2. Individuals whose genotypes are missing at the marker site cannot be taken into account.
3. QTL may be very far from all the markers if markers are widely spaced and hence the extent to which QTL may be detected will decrease.

### Interval Mapping

Interval mapping is popularly used for QTL mapping in experimental crosses. Interval mapping takes into account the use of a genetic map of the typed markers and assumes the presence of a single QTL. In this method, each locus is

considered one at a time, and the **logarithm of the odds ratio** (LOD score) is calculated. The odds ratio is related to the phenotype and the genotype of the marker for every individual in the cross, through Pearson correlation coefficient (Lynch and Walsh 1998). It is used to estimate the position of a QTL within two markers and was originally based on the maximum likelihood.

### Composite Interval Mapping (CIM)

In this method, interval mapping is performed, where marker loci are used as covariates. These markers act as surrogate for other QTLs to improve resolution of interval mapping by accounting for linked QTLs and minimizing the residual variation. One of the major disadvantages with this method is the selection of suitable marker loci which can serve as covariates.

### Family-Based QTL Mapping/Family Pedigree-Based QTL Mapping

Family-based QTL mapping involves multiple families instead of a single family. This type of mapping is the only way to map genes where

experimental crosses are difficult to make. It may include linkage and association mapping.

Linkage analysis is the primary tool for gene discovery, localization, and functional analysis and is the phenomenon whereby alleles at different loci cosegregate in families. Linkage between markers is calculated by odds ratios. Odds ratio is the ratio of linkage versus no linkage. This ratio is expressed as the logarithm of the ratio and is called a logarithm of odds (LOD) value or LOD score (Risch 1992). LOD values of  $>3$  are generally used for constructing linkage maps. A LOD value of 3 between two markers indicates that linkage is 1000 times more likely (i.e., 1000:1) than no linkage (null hypothesis). LOD values can be lowered for detecting a greater level of linkage or for including additional markers within maps that have been constructed at higher LOD values. The odds ratio provides a valid statistical method for using the family data to estimate the recombination frequency. The LOD score is represented as “Z.” Positive value of Z suggests that two loci are linked, whereas negative value indicates that linkage is less likely than the possibility that loci are unlinked. LOD score is calculated as under:

$$\text{LOD score} = Z = \log_{10} \left\{ \frac{\theta^{(\text{frequency of recombinants})} \times (1 - \theta)^{(\text{frequency of non recombinants})}}{1/2^{(\text{frequency of recombinants})} \times \frac{1}{2}^{(\text{frequency of non recombinants})}} \right\}$$

$\theta$  = probability of recombination

$1 - \theta$  = probability of non-recombination

The estimation of identity by descent (IBD) matrix is a very important component in mapping of QTL using variance component model. Alleles are identical by type (IBT) when they are producing the same phenotypic effect. There are two groups of allele which are identical by type:

- (i) Identical by descent (IBD) since they originated from same allele in previous generation
- (ii) Nonidentical by descent (NIBD) or identical by state (IBS) as they originated from separate mutations

Parent-offspring pairs have 50% of their genes that are identical by descent, and monozygotic twins have 100% genes that are identical among themselves by descent. In linkage analysis, inheritance of alleles at adjacent loci is important; therefore, it is critical to identify whether the alleles are identical by descent or only identical by state. Three categories of family-based linkage analysis are there; they have been summed up as under:

- (i) Strongly modeled (the LOD score model)
- (ii) Weakly modeled (variance components methods)
- (iii) Model-free

Lander and Kruglyak (1995) proposed certain criteria for reporting the significance of a linkage

relationship on the basis of standard genome scans in intercross and backcross populations. These criteria for statistical significance have now become standard practice: “highly significant” refers to  $p < 0.001$ , “significant” refers to  $p < 0.05$ , and “suggestive” refers to  $p < 0.63$  after correcting for multiple testing in a genome-wide scan. Permutation analysis is a more common approach that is likely to yield QTLs without affecting statistical significance. While reporting QTL map positions, the LOD score, the peak position, and an estimate of the confidence interval should be given. This allows to compare the map position with that for other QTLs that control potentially related traits. It may be possible that a QTL might fall outside a calculated confidence interval region owing to problems in marker order, genotyping errors, and/or model misspecification (Complex Trait Consortium 2003). In such cases, QTLs are difficult to identify, and overlaps between QTLs are difficult to determine. Any significant linkage should be confirmed before moving ahead for fine mapping.

### Construction of Linkage Map (Collard et al. 2005)

Linkage maps have been widely used in identification of chromosomal locations with genes and QTLs that are associated with traits of interest; such maps are referred to as “genetic” or QTL maps. There are three main steps of linkage map construction:

- (i) Production of mapping population
- (ii) Identification of polymorphism
- (iii) Linkage analysis of markers

The construction of linkage map requires a segregating population. Population size generally ranges from 50 to 250 individuals (Mohan et al. 1997). For linkage maps, which will be used for QTL mapping, it is important to note that mapping population must be phenotypically evaluated before proceeding for QTL mapping.

After production of mapping population, the next step is to identify polymorphic markers.

Once polymorphic markers have been identified, they must be checked across the entire mapping population including the parents. This process is known as marker genotyping of the population. Significant deviations from expected ratios can be analyzed using chi-square test. In general, markers will segregate in a Mendelian fashion; however, distorted segregation may also be encountered (Sayed et al. 2002; Xu et al. 1997). The final step in the construction of a linkage map involves coding data for each DNA marker on each individual of a population and conducting linkage analysis using computer programs. Though linkage analysis can be performed manually for a few markers, it is not feasible to manually analyze and determine linkages between large numbers of markers that are used to construct maps.

Software programs that are widely used are Mapmaker/EXP and MapManager QTX, which are freely available. “JoinMap” is also a commonly used software for constructing linkage maps (Stam 1993).

### Softwares for QTL Linkage Analysis

#### MapQTL

MapQTL is a program for the analysis of quantitative trait loci (QTL) in experimental populations of diploid species. MapQTL is a MS Windows program. This program can analyze QTL experiments with interval mapping, with MQM mapping, and with a nonparametric method. <https://www.kyazma.nl/index.php/MapQTL/>

#### QTL IciMapping (Meng et al. 2015)

QTL IciMapping is a software that is freely available, generally used for generating high-density linkage maps and mapping of QTL in biparental populations. Eight functionalities have been integrated in this software package. They are:

1. BIN: binning of redundant markers
2. MAP: construction of linkage maps in biparental populations
3. CMP: consensus map construction that is generated from multiple linkage maps which share common markers

4. SDL: mapping of segregation distortion loci
5. BIP : mapping of additive, dominant, and digenic epistasis genes
6. MET : QTL by environment interaction analysis
7. CSL : mapping of additive and digenic epistatic genes which have chromosome segment substitution lines
8. NAM : QTL mapping in NAM (nested association mapping) population

Input files are usually plain text, MS Excel 2003, or MS Excel 2007 formats. The prefix name is similar for output and input files but with different extensions.

## Conclusion

The genomic regions that contain genes which are associated with a particular quantitative trait are known as quantitative trait loci. Multiple genes control the expression of quantitative traits. The use of DNA markers with construction of linkage maps is vital for identifying chromosomal regions that contain genes controlling simple traits and quantitative traits using QTL analysis. Application of QTL linkage analysis is an important tool for identifying genomic regions associated with traits. Once QTL has been identified, molecular techniques can be employed to narrow down QTL to candidate gene. One of the major drawbacks in QTL analysis is at the level of phenotyping.

Genome-wide association studies (GWAS) have been a popular tool in genetic research, and they are an excellent complement to QTL mapping. Whereas QTL contain many linked genes, GWAS produce many unlinked individual genes and sometimes even nucleotides. Though GWAS remain limited to organisms with genomic resources, combining GWAS, the two techniques can utilize most of both approaches. Although GWAS, next-generation sequencing, and many other high-throughput robust techniques came into picture during the past few years, the use of linkage analysis is still a very precise classical technique for identifying novel candidate genes and potential candidate genes.

QTL studies have a long and rich history and have played important roles in gene cloning and characterization; however, there is still a great amount of work to be done. The available data on model organisms should be expanded to the point where meta-analysis is practically possible in order to account for robust trends with regard to genetic architecture. Moreover, QTL studies can be an important tool for studying functional genomics as well, where allelic variation is characterized. The correlation between genotype and phenotype is still difficult to evaluate, but QTL analysis will likely continue to provide key advancements in functional genomics.

## Synonyms

Grasping hands and feet

## Definition

Having both hands and feet that are capable of grasping

In the most basic sense, *quadrumanous* represents the anatomical and neuromuscular modification of the *hands and feet* that allows them similar functional roles of grasping onto supports or other objects (Boyer et al. 2013; Gebo 1985; Napier 2009). Traditionally the term *quadrumanous* has been applied only to the nonhuman primates, but it is important to note that such an anatomical configuration has evolved in other tetrapod lineages, albeit rarely (Sustaita et al. 2013; Fig. 1). The most notable are the highly arboreal lizards of the family Chamaeleonidae. In these animals, the digits of the feet and hands are organized into bundles (i.e., group of two and a group of three digits) which oppose one another to grasp branches in a pincer-like arrangement (Sustaita et al. 2013). The *quadrumanous* configuration of the hand and foot is also observed in the arboreal anteaters (*Tamandua* and *Cyclopes*) and sloths (*Choloepus* and *Bradypus*) (Godfrey et al. 2016; Granatosky 2016). In these animals, a reduction of the digits has essentially modified the hands and feet into large hooks. A similar condition, albeit without the digital reduction, is observed in the colugos. These animals are able to utilize these hooks as grapples to maintain security during arboreal locomotion (Granatosky 2016).

In the nonhuman primates, a different pattern of grasping has evolved where the first digit (i.e., pollex in the hand; hallux in the foot) is divergent from the rest of the digits (Boyer et al. 2013; Gebo 1985; Napier 2009). This configuration allows for opposition of the pollex and hallux against the other digits, therefore allowing the generation of grasping forces (Cartmill 1985; Napier 2009). Interestingly, the grasping ability of the hand and foot did not evolve in synchrony. Early primates appeared to have evolved grasping abilities first in the foot, while the hand retained a claw-clinging grasp (Boyer et al. 2013). This configuration is typical of many of the living arboreal didelphids (Cartmill 1985). Only at the origins of Euprimates did the “typical” *quadrumanous* configuration of

**Quadrumanous, Fig. 1** Examples of quadrumanous grasping in tetrapods

the hands and feet arise (Boyer et al. 2013). Anatomical evidence for grasping extremities in primates are usually characterized by a lack of nails, elongated digits, and a divergent pollex and hallux (Boyer et al. 2013; Cartmill 1985; Gebo 1985).

The functional and evolutionary origins of the *quadrumanous* condition have invariably been linked to the challenges of moving on thin arboreal supports (Cartmill 1985). The terminal ends of branches provide important foraging locations for animals, as they are often the site of young leaves, fruit, blooming flowers, and insect prey. Access to these branches, however, is difficult for animals of relatively large body and presents these animals with novel mechanical challenges compared to movement on larger diameter supports (Granatosky et al. 2016). As the body size to support size ratio increases, the tendency to topple off the support also increases (Cartmill 1985; Grand 1972). One solution to this balance problem may be for arboreal animals to move their center of mass below branch, thereby adopting suspensory behaviors (Cartmill 1985; Granatosky 2016; Grand 1972). This is the condition for orangutans,

colugos, and sloths. In these animals, the hands and feet are modified into *quadrumanous* hooks that prevent the animal from falling off the support (Godfrey et al. 2016; Granatosky 2016).

In contrast, non-suspensory arboreal quadrupeds (e.g., primates and chameleons) use powerful grasping musculature to overcome the toppling torques imposed upon the body (Boyer et al. 2013; Cartmill 1985; Gebo 1985). While the presence of grasping feet alone seems to be enough to overcome these toppling torques (e.g., arboreal didelphids) (Cartmill 1992; Sustaita et al. 2013), it is likely that the *quadrumanous* condition observed in primates and chameleons has allowed for the invasion of the fine branch niche and exploitation of the resources available within this environment (Boyer et al. 2013; Cartmill 1985; Grand 1972).

## Definition

Movement using a combination of four limbs.

**Quadrupedal** locomotion encapsulates any form of progression in which four limbs support and propel the body. **Quadrupedal** movement represents the basal condition for all tetrapods and as such remains the most commonly utilized form of locomotion (see Fig. 1 and Granatosky 2018 for data on mammals). Interestingly, the origins of **quadrupedal** locomotion appear to predate the invasion onto land by tetrapods. Experimental studies on living sarcopterygians (i.e., lungfish and coelacanths) demonstrate that the neuromuscular patterns and functional subdivisions of the “limbs” required for effective **quadrupedal** locomotion were likely present in fully aquatic tetrapod ancestors prior to the invasion onto land (Aiello et al. 2014; Décamps et al. 2017; Fricke and Hissmann 1992).

**Quadrupedal** locomotion is usually categorized as symmetrical or asymmetrical based on kinematics and then further subdivided into walking and running on the basis of either kinematics or kinetics (Fig. 2; Alexander 2003; Cavagna et al. 1977). Symmetrical gaits occur when footfalls of the forelimb and hindlimb are evenly spaced in

**Quadrupedal, Fig. 1** The percentages of locomotor behaviors observed for extant mammals. (Adapted from Granatosky (2018))

time (e.g., walk, pace, or trot). Asymmetrical gaits (e.g., gallop and bound) occur when the actions of the forelimb or hindlimb are unevenly spaced in time. A kinematic definition of a walking gait is one with a duty factor over 50%, while gaits with duty factors less than 50% are considered a run. A duty factor is simply the percent of the total cycle which a given foot is on the ground. Alternatively, it is possible to divide walking and running based on center of mass mechanics (Cavagna et al. 1977). During walking, the center of mass is analogous to a swinging inverted pendulum. With this mechanism, kinetic and potential energy are exchanged out of phase with each other as the animal's center of mass rises and falls throughout a stride. During running gaits (e.g., hopping, trotting, or galloping), center of mass movements move in phase with one another, analogous to a spring or bouncing ball. In mammals, the kinematic and kinetic definition of walking and running tend to describe the same behavior. However, recent work looking at the center of mass mechanics in reptiles and amphibians demonstrates the relationship is less clear (Reilly

et al. 2006). As such, further discussion in this chapter will be reserved to kinematic patterns.

## Walking Gaits

All walking gaits are symmetrical and involve two general patterns at which animals move their limbs (Alexander 2003). A lateral-sequence gait is one in which each hindlimb footfall is followed by an ipsilateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb). A diagonal-sequence gait is one in which each hindlimb footfall is followed by a contralateral forelimb footfall (i.e., right hindlimb, left forelimb, left hindlimb, right forelimb). Commonly, during walking gaits the forelimbs and hindlimbs are traveling together as a slightly asynchronous couplet. When the ipsilateral forelimbs and hindlimbs are traveling together, this is referred to as a lateral couplet; when the contralateral forelimbs and hindlimbs are traveling together, this is referred to as a diagonal couplet. Very rarely do the limbs move together in perfect synchrony.

**Quadrupedal, Fig. 2** Gait graphs. Dark areas indicate times of contact; bottom axis is % of cycle. RH = right hindlimb; LH = left hindlimb; RF = right forelimb; LF = left forelimb

Lateral-sequence lateral-couplet footfall patterns tend to be present in long-legged terrestrial animals and are assumed to be the best mechanism to prevent interlimb interference. However, this footfall pattern is thought to be inherently unstable because a majority (~66%) of the stride is spent as a unilateral bipod (i.e., only two ipsilateral limbs in contact with the support), which tends to roll the body side-to-side throughout the stride. This instability is argued to be negligible for long-legged animals but can be devastating for short-limbed broad-chested quadrupeds. For these species, lateral-sequence diagonal-couplet footfall patterns tend to be more common. This footfall sequence is inherently more stable than lateral-sequence lateral-couplet gaits due to the generally low proportion of the stride spent as a unilateral bipod (~22%) and the relatively high proportion of the stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed

limbs in contact with the support). In general, foot positions arranged as diagonal bipods and large tripods are thought to be highly stable (Cartmill et al. 2002).

Primates and other highly arboreal mammals tend to use diagonal-sequence diagonal-couplet footfall patterns when moving along relatively thin arboreal supports (Cartmill et al. 2002; Granatosky et al. 2016; Hildebrand 1967). This gait pattern maximizes the proportion of the stride in which the limbs are arranged as a widely splayed diagonal bipod and ensures that one of the grasping hindfeet is placed in a protracted position (and thus lies roughly underneath the animal's center of mass) on a tested support at the moment when the contralateral forefoot strikes down on an untested support during arboreal locomotion (Cartmill et al. 2002; Lemelin and Cartmill 2010). The legitimacy of this adaptive scenario for diagonal-sequence diagonal-couplet gaits has received considerable debate (see

Shapiro and Raichlen 2005). Diagonal-sequence lateral-couplet gaits are rarely observed in nature and are considered highly unstable.

## Running Gaits

The trot, pace, and amble are symmetrical *quadrupedal* runs. All running gaits include some period of the cycle in which no feet are touching the ground (i.e., an aerial phase). In trotting, diagonally opposite feet move in phase with each other; in pacing, the two feet on the same side of the body move in phase with each other; and in ambling, the four feet move at roughly equal intervals, in the same order as in walking. Most quadrupeds trot when traveling at moderate speeds, but camels' pace and elephants sometimes amble (Alexander 2003; Hildebrand 1976).

At high speeds, *quadrupedal* mammals use asymmetrical gaits, generally making the change from a trot or pace to a gallop. Early studies (Muybridge 1887) identified two fundamental types of gallop variously called the diagonal or transverse gallop and the lateral or rotary gallop. These were fully described in detail in the classic paper by Hildebrand (1959), where the transverse gallop is epitomized by the horse and the rotary gallop by the cheetah (Fig. 3). The canter, which is recognized by horse riders as a distinct gait, is a form of galloping used at low speeds. Galloping mammals arch their backs during the part of

the stride when the fore feet are on the ground and straighten them while the hind feet are on the ground (Alexander 2003).

In general, running gaits in reptiles are usually constrained to trotting. However, some crocodilian species are capable of adopting asymmetrical galloping gaits. This is exemplified in the Australian freshwater crocodile (*Crocodylus johnstoni*). The crocodilian gallop has been described as the fore- and hindlimbs working in serial pairs similar to that of a bounding gait (Fig. 3). However, these movements are highly variable, and animals have been recorded using a transverse or rotary gallop, a half bound, or a bound (Renous et al. 2002; Zug 1974). This diversity of asymmetrical gaits in *C. johnstoni* is not overly surprising considering patterns of rhythmicity in bradymetabolic (poikilothermic) tetrapod lineages (Ross et al. 2013).

## Gait Transitions

A general feature of *quadrupedal* locomotion by mammals is that, as they increase speed, they switch between gaits (e.g., walk, run, trot, gallop) (Griffin et al. 2004; Hoyt and Taylor 1981). While numerous studies have characterized gait transitions from kinematic, kinetic, and metabolic perspectives, the mechanism triggering gait transitions remains unclear.

The most commonly cited function of gait transitions is to minimize energetic expenditure

**Quadrupedal, Fig. 3** Examples of a transverse gallop in a horse (a) and a rotary gallop in a cheetah (b) and crocodile (c)

(Griffin et al. 2004; Hoyt and Taylor 1981). In an idealized situation, plots of energetic cost of transport per unit distance (COT;  $\text{J kg}^{-1} \text{m}^{-1}$ ) against locomotor speed reveal intersecting curvilinear relationships for different gaits (e.g., walking, trotting, galloping) (Griffin et al. 2004; Hoyt and Taylor 1981). The peaks of the lines are locomotor speeds with a high COT, and the valleys are speeds with lower energetic costs. For the most part, when animals are allowed to move at self-selected speeds, they select the most economical speeds within a given gait type and avoid speeds that are more energetically costly (Griffin et al. 2004; O'Connor et al. 2012). However, as animals adopt speeds near the peaks of their gait-specific COT curves, energy costs increase rapidly. This makes it energetically costly to maintain those gaits, and gait transitions become critical for energy conservation (Griffin et al. 2004; Hoyt and Taylor 1981).

This energy minimization hypothesis for gait transitions is not without its critics (Brisswalter and Mottet 1996; Farley and Taylor 1991). In light of limitations to the energetic minimization hypothesis, a number of studies have proposed that animals use mechanical triggers to make gait transitions to preemptively limit high stresses on the bone (Biewener and Taylor 1986; Farley and Taylor 1991). As first observed by Farley and Taylor (1991), at the transition from a trot to a gallop, peak forces on the muscles, tendons, and bones, and presumably the chance of injury, are significantly reduced. Furthermore, when animals move with added weight, they switch from a trot to a gallop at a lower speed but at the same critical level of force. However, no such effect is observed during the transition from a walk to a trot or during the trot to gallop transition in small mammals (Iriarte-Díaz et al. 2006). Taken together, this evidence suggests that the forces applied to the musculoskeletal system likely do not trigger gait transitions, at least at the walk-trot transition.

An alternative approach to understanding gait transitions emerges from considering stability. When animals adopt speeds close to the optimal stride length and frequency for a particular gait type (e.g., walking or trotting), locomotion is

stable, highly rhythmic, and energetically efficient (Diedrich and Warren 1995; Granatosky et al. 2018; O'Connor et al. 2012). However, when an animal is forced to speed up or slow down, it enters more variable, potentially unstable locomotor conditions (Brisswalter and Mottet 1996; Diedrich and Warren 1995; Jordan et al. 2007). This suggests that unstable, highly variable locomotor states, like those preceding a gait transition, are noisier and less predictable than steady-state movement (Brisswalter and Mottet 1996; Granatosky et al. 2018; O'Connor et al. 2012). Sensorimotor feedback about these unstable conditions could help guide the animal to a new stable locomotor state (Granatosky et al. 2018). In this stability context, it has been suggested that gait transitions serve to reduce locomotor variability and avoid unstable states that might lead to injury or unnecessary energy expenditure (Brisswalter and Mottet 1996; Diedrich and Warren 1995; Granatosky et al. 2018).

## Qualitative Disorders

F. Nghakliana and Zothansiamia

Department of Zoology, Mizoram University,  
Mizoram, India

### Definition

Qualitative disorders are the type of genetic disorders that arise from change(s) in a single gene leading to suppression or abnormal expression of a gene causing corresponding phenotype with no intermediate form. The phenotypic representations are qualitatively accessible and not quantitatively.

### History

The linking of medical conditions with the concept of genetics was first done by Archibald Garrod in 1902 when he studied the recessive nature of inheritance of the disorder alkaptonuria, a rare genetic disorder which is characterized by the accumulation of homogentisic acid in the body due to mutation of the homogentisate 1,2-dioxygenase (HGD) gene. Later in 1911, E. B. Wilson then mapped the gene for color blindness to the X chromosome, and since then, about 36 X-linked disorders were mapped within the next 40 years (Kennedy 2005). According to the Online Mendelian Inheritance in Man (OMIM), approximately 4000 qualitative disorders have been identified.

## Autosomal Recessive Qualitative Disorders

The qualitative disorders that arise from mutation of the recessive allele of autosomes are called as autosomal recessive qualitative disorders. Being recessive, only homozygous condition will cause the disorder to manifest, i.e., both copies of the mutated recessive alleles need to be present. For a child to be affected, both the defective alleles must be inherited from both the parents, i.e., both the parents must be either carrier or affected individuals. With two carriers, there is 25% of having an unaffected normal child, 25% of having an affected child, and 50% of having an unaffected carrier child.

## Autosomal Dominant Qualitative Disorders

This type of qualitative disorders arise when there is a mutation of a dominant allele of a gene that will cause the manifestation of the disorder in both homozygous and heterozygous states. Individuals with such disorder have 50% chance of transmitting the disorder to their children. Examples of such disorder are Huntington disease, polycystic kidney diseases, neurofibromatosis, etc.

### Huntington Disease

Huntington disease is an autosomal dominant qualitative disorder that arises when there is a mutation in the huntingtin (HTT) gene located on the short arm of chromosome 4 that causes neuronal degeneration in the brain (National Institute of Neurological Disorder and Strokes 2019). The HTT gene has a trinucleotide repeat (CAG) that shows variations in length from individual to individuals. Dynamic mutation often results in increase in the number of trinucleotide counts resulting in a defective gene producing an altered mutant protein (mHTT), thereby causing different pathological changes in the body such as increased rate of neuronal death. Normally, the HTT gene is highly expressed in neurons, and its absence was found to induce embryonic death in mice (Nasir et al. 1995);

however, its primary function in human remains unclear. The physical symptoms of this disorder, collectively called as chorea, are first observed between the ages of 35 and 40. Chorea includes jerky and random movements. However, the cognitive and behavioral symptoms are not easily recognizable. Since the penetrance of the mHTT is high, even a single copy of the mutated allele is enough for the disorder to manifest.

### Phenylketonuria

Phenylketonuria (PKU) is an autosomal recessive qualitative disease that arises due to mutations in the PAH gene on chromosome 12 that encode the phenylalanine (Phe)-hydroxylating enzyme called phenylalanine hydroxylase (PAH; EC 1.14.16.1) that results in a production of a non-functional PAH enzyme. If untreated, blood level of Phe concentration is elevated and causes severe mental retardation with reduced levels of dopamine, catecholamine, and serotonin apart from other symptoms (Groot et al. 2010). Being a recessive condition, for this disorder to manifest, both the copies of the mutated alleles are required to be present. If both parents are carriers, the chance of a child being born with PKU is 25%. PKU remains incurable. However, upon early diagnosis, a child can be treated to minimize neurological damages through the management of the level of Phe in the system either through diet or medications or both.

### Sex-Linked Qualitative Disorder

Certain qualitative disorders are caused due to mutation of genes that are located on the sex chromosomes, usually the X chromosome. Such disorders are called as sex-linked qualitative disorders. The mutated/deleted allele may be either recessive or dominant. For X-linked disorders, in recessive form, a homozygous condition is also required for the disorder to occur. An affected female will always transmit the disorder to her son, while her daughter will simply be a carrier, unless both parents are affected. In dominant form, only a single allelic copy is sufficient, and an affected male will always transmit the disorder to

his daughter but never to his son. The common sex-linked qualitative disorders are hemophilia, X-linked hypophosphatemia, thalassemia, red-green color blindness, Duchenne muscular dystrophy, glucose-6 phosphatase deficiency disorder, etc.

### Hemophilia

Hemophilia is an X-linked recessive disorder that arises due to mutation in the gene for the clotting factors VIII (hemophilia “A”) and IX (hemophilia “B”) that compromises the activation of factor X during the process of blood coagulation and result in failure of blood to clot even in minor injuries. Point mutation in these gene is the most common mutation and accounts for 90% of all hemophilia. Such point mutations are usually missense, nonsense, or splice site point mutations (Bowen 2002). Deletion of the whole gene occurs in 5–10% of hemophilia. X-linked recessive disorders, including hemophilia, affect male more than female since female have two copies of X chromosome in which the one that carries the normal allele may compensate for the mutated genes. However, such female remains a carrier and has a 50% chance of transmitting the mutated genes to her offspring. The major problem associated with the treatment of hemophilia is the synthesis of antibodies against the infused clotting factors administered to the patient via replacement therapy. Researches have been going for the application of gene therapy for the treatment of hemophilia; however, this remains an unapproved strategy (National Heart, Lung, and Blood Institute 2013).

### X-Linked Hypophosphatemia

X-linked hypophosphatemia is an X-linked dominant disorder which exhibits ricket/osteomalacia-like symptoms that arise due to the mutation of the PHEX gene which is involved in the mineralization of bone and dentin. One important function of PHEX is the regulation of renal phosphate reabsorption by inhibiting the activity of fibroblast growth factor 23 (FGF-23) that promotes renal reabsorption of phosphate. Mutation of PHEX results in overactivity of FGF-23 and thus causes an excessive reabsorption of phosphate, thereby leading to

hypophosphatemia in the bloodstream (Farzana et al. 2007). In 2018, the FDA approved immunotherapy with the monoclonal antibody “Burosumab” for the treatment of X-linked hypophosphatemia (Carpenter et al. 2018).

## Symptoms of Qualitative Disorders May Be Pleiotropic Effect

Pleiotropy is the phenomenon where a single gene may have more than one phenotypic effect. This pleiotropic effect of a single gene may give rise to the different phenotypic representations of a qualitative disorder. For example, the monogenic disease Marfan syndrome is caused by either an inherited or sporadic mutation in the FBN1 gene located on chromosome 15. The FBN1 gene primarily encode for the microfibril Fibrillin-1 which forms part of the microfibrils in the heart valves and aorta along with Fibrillin-2 (Quondamatteo et al. 2002). The mutation in the FBN1 not only cause impairment in the structure of the heart valves but also exhibit other phenotypic symptoms such as thoracic scoliosis, thin and long limbs and digits, etc.

## Conclusion

Qualitative disorders are responsible for a heavy loss of life globally. The global prevalence of all single gene diseases at birth is approximately 10/1000 (Scriver 1995). Complete cure of qualitative disorders seems a far-fetched achievement as of now, although medications and replacement therapy are successfully employed for symptomatic treatment. Gene therapy, where the defective gene is replaced by a normal gene, has become promising for the definite cure of such disorders and is still a huge area of biomedical research.

## Introduction

Most traits have a continuous spectrum and cannot be classified in discrete, qualitative categories such as height, weight, blood pressure, etc. Quantitative genetics is the field of genetics which deals with the study of continuously varying characters such as height, weight, blood pressure, etc. Continuous variation that is observed is usually because the traits are polygenic (when more than two genes control a particular type of trait or traits) and also there are environmental effects that has their own effect on the phenotypic state of each individual (Anderberg 1973; Mendel and Bateson 1891a, b; Steel and Torrie 1980; Hill 2010). To explain the effect of environmental factors on gene expression, let's understand it by this example, temperature is an environmental factor. Himalayan rabbits carry C gene which is temperature sensitive and is responsible for different coat colors of rabbits. This gene is active below 30 °C and inactive above 30 °C. Thus the rabbits that stay at cold temperature have pigmented body.

Traits which are controlled at single gene locus are called as Mendelian traits. These traits have two alleles dominant and recessive, inherited one from each parent. Dominant allele is expressed in both homozygous and heterozygous conditions, while recessive allele is expressed only in homozygous condition. One of the major differences between quantitative and Mendelian (qualitative) traits is the number of genes controlling them.

Each participating gene follows the Mendelian trait rules with each of them having some effect on the trait; this is called as polygeny. Another important difference between quantitative and qualitative traits is their sensitivity to environmental factors. Suppose our genes have the potential of gaining weight up to 75 kg, but if we don't have good nutrition and food while growing up, we might not reach this weight. So, in the case of quantitative traits, phenotypic variation (designated VP) is primarily the combination of variation resulting from different sources: variation from genetic effects (designated VG) + variation resulting from environmental effects (designated VE) (Hill 2010; Goddard et al. 2016). Understanding it with an example, in a herd of sheep, each and every sheep has different body weight and woollen fleece thickness. This phenotypic variation (VP) is because of the different (VG) and the type of condition, i.e., water intake, food intake, and sleep pattern (environmental factor) (VE) they had.

$$VP = VG + VE$$

Other factors, such as variation resulting from interactions between genetic and environmental effects (designated VGE), are also important in quantitative genetics. In contrast to qualitative traits, there is no simple relationship between genotype and phenotype, so in order to study them, different approaches are used.

**Additive genetic variance (VA):** Each participating allele has a specific effect on the phenotype. Potentially or in other words we can say this is one of the most important variance wrt the dominance and interaction variance. For example diabetes is a polygenic disorder. Multiple genes are involved in the pathogenesis of diabetes mellitus.

**Dominance genetic variance (VD):** This is similar to the Mendelian inheritance. In this case, we have the same relationship between alleles at a single locus as we discussed in classical Mendelian inheritance. Since presence of one dominant copy is enough, homozygous dominant and heterozygous genotypes contribute equally to the phenotype (effect of HH = effect of Hh). Recessive allele will not be able to show its effect

in heterozygous condition (Hh) and can only show its effect when present as homozygous copies (hh). For example, in sickle cell disease presence, one defective gene copy doesn't have serious effect on the person carrying it, while if mutant gene is present in two copies, then the person will have adverse outcomes.

**Epistatic variance or interaction genetic variance (VI):** in this type of variance, different loci interact to affect the trait. By "interaction" we mean usually an effect on the phenotype beyond additive. In additive effect, multiple genes culminate to produce a particular type of effect, while in interaction effect, for example, in epistatic variance, one gene masks the effect of other gene, and this way the variation thus observed is because of interaction of multiple genes.

Example of additive variance:

Example of interaction variance:

Thus the genetic variance can be partitioned into additive (VA) and dominance (VD) components:  $VG = VA + VD + VI$ . (VI = Interactive Variance).

The total phenotypic variance is thus partitioned:  $VP = VA + VD + VI + VE$ . (VE = Environmental Variance).

## Heritability

The general term that describes the proportion of the genetic variance to the total variance is

heritability. Two specific types of heritability can be estimated. Heritability denotes the proportion of phenotypic variance that is due to genotype.

The broad-sense heritability is the ratio of total genetic variance to total phenotypic variance (Hill 2010). We can understand few important things from the mentioned definition: it's entirely open in the respect that how specific genetic effects contribute to VG. Broad-sense heritability isn't affected irrespective of whether VG is the outcome of one gene's single Mendelian variant, or the small additive effects from variants in 100 different genes, or complex interactions between every variant in the whole genome.

$$H^2 = VG/VP$$

The narrow-sense heritability is the ratio of additive genetic variance to the total phenotypic variance (Hill 2010). In other words, what proportion of phenotypic variation in the given population is due to the genetic effects which can be inherited in offspring from their parents  $h^2 = VA/VP$

The narrow-sense and broad-sense heritability are the same under the condition when there are no dominant, recessive interaction, and also it is to be noted that narrow-sense heritability will be smaller since it excludes (i.e., VG) these other types of genetic effects.

effects, as was the case for Gregor Mendel's pea plant seeds being smooth or wrinkled, yellow or green. Instead, many complex traits, diseases, and disease susceptibilities are influenced by interactions between alleles at multiple genetic loci that each exerts quantitative effects on a phenotype, commonly producing a continuous phenotypic distribution. These traits are polygenic (i.e., influenced by multiple genes) and often multifactorial (i.e., can be further influenced by environmental factors). When polygenic or multifactorial traits present with numerical phenotypic variation, they are additionally termed “quantitative traits” (Consortium 2003).

## Quantitative Trait Loci (QTL)

Luke Brandenberger  
University of Utah School of Medicine, Salt Lake City, UT, USA  
Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), Bethesda, MD, USA

### Definition

Quantitative Trait Loci (QTL) are genetic segments containing one or more genes that correlate with phenotypic variation in a quantitative trait.

### Introduction

Advances in DNA sequencing over the last 25 years have reduced the cost to generate a high-quality draft of the human genome from hundreds of millions to less than \$1,500 (Wetterstrand 2018). The ease of access to sequence data has led to remarkable growth and demand for sequence analysis – how changes in genes and gene expression contribute to morphology and disease. For scientists, the process of connecting a phenotype to a gene can be complex. Many human traits and diseases are not solely determined by alleles at a single genetic locus that produce discrete “all-or-none” phenotypic

## Quantitative Trait Loci (QTL)

Quantitative Trait Loci (QTL) are physical chromosomal segments containing one or more genes that contribute to variation in a quantitative trait. QTLs are identified by observing the inheritance of variation in a quantitative trait and then linking that variation to the inheritance of molecular markers (e.g., sequence variation, usually in noncoding DNA) across several generations of plants, experimental lab animals, or human families. Passage of the molecular markers with a change in degree of a quantitative trait may suggest that the sequence between these two inherited markers contains at least one gene contributing to the phenotype. QTL mapping is useful for identifying genomic regions that can be further analyzed for candidate genes or alleles underlying a change in a multifactorial trait or disease.

Quantitative traits typically present with continuous variation that forms a normal distribution due to the contributions of multiple additive genetic loci. Height, blood pressure, skin color, and body mass all form bell-shaped distributions in large populations (Jorde et al. 2016). This is the result of Mendelian inheritance at multiple loci, also termed polygenic or quantitative inheritance. This is distinguished from pure Mendelian inheritance in that multiple loci allow for combinations of alleles and polymorphisms that may each exert varying effects on the phenotype. These loci are often unlinked, possibly on

separate chromosomes, allowing for independent assortment of contributing loci to offspring.

Human height, for example, is estimated to be 90% determined by inheritable factors spread over 180 identified genetic loci (He et al. 2015). At each locus, alleles may exist in a population that exert relative height decreasing (aa), or height increasing (AA) influences. Assuming non-dominance, the three possible phenotypic effects at any loci are decrease height (aa), maintain height (Aa), or increase height (AA). If we assume that the alleles functioning to increase and decrease height are present in equal frequencies, then at any single loci 50% of offspring will have a height increasing or maintaining influence (Aa), 25% will contain height decreasing influence (aa), and 25% will contain height increasing influence (AA). Alleles at any locus may be recessive, dominant, or co-dominant. This process repeated at many additive loci will typically result in a bell-shaped curve, a normal distribution (Fig. 1).

The phenotypic effects of individual QTL may be dependent on complex interactions between other factors and have variable impact on the phenotype of their associated trait. Gene-gene and gene-environment interactions are common and can impede QTL identification, particularly when a phenotype is controlled by numerous loci that produce relatively small effects, termed

modifier loci. Notably, quantitative traits may be influenced by other loci that seem to produce significant discrete effects that are indistinguishable from Mendelian traits. (Miles and Wayne 2008). Returning to human height, the majority of loci exert minute effects, otherwise we would not see a normal distribution in populations, yet a few generate significant changes in phenotype. For example, a mutation in a transmembrane domain of the fibroblast growth factor receptor *FGFR3* produces a significant reduction in height diagnosed as achondroplasia, the most common form of dwarfism. This type of control is common in quantitative traits, with a typical phenotype affected by a few loci producing discrete or Mendelian effects and numerous modifier loci of minute effect (Remington and Purugganan 2003).

### Quantitative Trait Loci in Multifactorial Disease

The majority of the human disease burden has a genetic component – disease or disease risk is inheritable by offspring (Jorde et al. 2016, p. 239). Genetic conditions can be broadly sorted into two types: disease induced by mutation at a single loci (e.g., cystic fibrosis, Duchenne

#### Quantitative Trait Loci (QTL),

**Fig. 1** Quantitative trait alleles forming a normal distribution

muscular dystrophy) or disease that is attributable to multiple genetic and environmental influences. Multifactorial disease, the latter category, represents the majority of human conditions and includes cancer, diabetes, dementia, and heart disease (Stolk et al. 2008). Since these ailments are influenced by interactions of multiple loci, and the environment, they follow polygenic or quantitative inheritance. Yet, instead of a phenotypic bell curve, multifactorial diseases often appear to be either present or absent. For many diseases, a threshold of risk must be passed before a disease is expressed. Commonly, alleles circulating in populations may predispose individuals to a disease, exert no effect on disease risk, or be protective. Thereby, multifactorial disease risk in populations forms a bell curve similar to quantitative traits, termed a liability distribution. Individuals with higher numbers of disease-causing alleles will be more likely to develop disease, while individuals with noncausative or protective alleles will be at lower risk (Fig. 2).

Quantitative trait locus analysis conducted on multifactorial disease can yield biomarkers correlating to disease risk, progression, and lethality. One example is the discovery of mutations in the well-known homologous DNA repair proteins *BRCA1* and *BRCA2* that lead to 69–72% risk of developing breast cancer by age 80, in addition to

an increased risk of stomach, pancreatic, and colon cancer (Kuchenbaecker et al. 2017). Following the discovery of these markers, the US Preventive Services Task Force (USPSTF) issued a recommendation for *BRCA1/2* screening for women with a family history of breast, ovarian, fallopian, or peritoneal cancer (Moyer 2014). However, it is estimated that *BRCA1/2* mutations account for only up to 30% of the total inherited cases of breast cancer, implying that rare or less penetrant mutations in other loci compose the majority of genetic risk (Economopoulou et al. 2015).

Conclusion

Intensive efforts have already identified diverse QTL that contribute to the development of many diseases and brought multigene panels into clinical use that screen for common and rare mutations in patients with familial risk. Further research into novel gene-gene and gene-environment interactions that underlie human traits, disease risk, and progression is of continuing scientific interest. The ease of access to genome sequencing will allow researchers and clinicians to increasingly personalize care and better target high risk individuals for screening and preventative treatments.

Quantitative Trait Loci (QTL),

## Radial Arm Maze

Jitendra Kumar Sinha<sup>1,2</sup> and Shampa Ghosh<sup>3</sup>

<sup>1</sup>CSIR – Centre for Cellular and Molecular Biology (CCMB), Hyderabad, Telangana, India

<sup>2</sup>Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

<sup>3</sup>Endocrinology and Metabolism Division, National Institute of Nutrition (NIN), ICMR, Tarnaka, Hyderabad, India

## Synonyms

[Apparatus to measure spatial learning and memory](#)

## Definition

A radial arm maze is an apparatus with multiple equidistant arms connected to a central platform, which is used to study spatial learning and memory in animals, primarily rodents.

## Introduction

The original eight-arm radial arm maze (RAM) was designed by David S. Olton and Robert J. Samuelson in 1975 at The Johns Hopkins University. The maze was designed to assess cognitive functions like spatial learning and memory in rodents and other animals (Olton and Samuelson 1976). As shown in Fig. 1, an individual animal is placed in the central platform and allowed to freely explore the maze. Typically, the ends of each maze arm are baited with food rewards, which the animal can retrieve. If the animal remembers where it has been, it should avoid revisiting arms in which it has already retrieved the food rewards.

The RAM is a noninvasive technique, which has been well validated all across the globe (Kandel et al. 2014; Olton et al. 1977; Saxe et al. 2007) and thus can be easily modified to assess the effects of environmental, pharmacological, or surgical interventions on behavior (Samuelson et al. 2016). In addition, the number, size, and substrate of the arms can be modified to suit the foraging techniques used by different species, including insects, birds, and even humans (Mennenga et al. 2014; Samuelson et al. 2016).

**Radial Arm Maze, Fig. 1** Schematic diagram showing the structure of a typical radial arm maze (RAM)

**Radial Arm Maze, Fig. 2** Schematic diagram showing the usage of radial arm maze (RAM) for testing **Reference memory**

## Types of RAM

Using the RAM task, researchers can assess different types of memory:

1. **Working Memory:** In the standard RAM task, all the arms are baited with a food reward, as shown in Fig. 1. To perform perfectly, an animal should visit each arm only once. If the animal visits one or more arms more than once or visits non-baited arm, it is counted as a working memory error.
2. **Reference Memory:** In this test a subset of the arms of the maze are baited with a food reward, and these arms remain constant throughout testing. As shown in Fig. 2, an animal should visit only the baited arms. Visiting the same baited arm more than once or visiting non-baited arm is considered as reference memory error.

## Conclusion

To summarize, the RAM is used for the assessment of spatial working and reference learning and memory in animals. The radial arm maze can be easily modified to investigate different aspects of behavior and cognition.

### Definition

Radial symmetry can be defined as the body plan of those animals, which can be divided into two equal halves if they are cut through any of the radial planes.

### Introduction

Body symmetry stands for the characterization of body plan and can be defined as the similarity of parts in different regions and directions of the body. Based on symmetry, the animals can be divided into asymmetrical, radially symmetrical, and bilaterally symmetrical animals. Animals that cannot be divided into two equivalent halves through any plane are described as asymmetrical animals, e.g., sponges, adult snails, etc. Animals that can be divided into two equivalent halves if they are cut through any of the radial planes are described as radially symmetrical animals, e.g., jellyfish, corals, sea anemones, etc. Animals which can be divided into two equal right and left halves only if they are cut in the vertical plane passing through their median longitudinal body axis, e.g., flatworms, earthworms, and humans, are known as bilaterally symmetric

(Playfair and McMurrich 1896). Exact spherical symmetry is not found in the animal body plans.

## Radial Symmetry

A radially symmetrical animal can be divided into equal portions from its center, much like that of cutting a pizza into slices. These animals do not possess head (anterior) and tail (posterior) or left and right regions. Such symmetry allows animals to reach out in all directions from one central point, though at a much slower speed as compared to the bilaterally symmetrical animals. Moreover, their sensory organs are generally scattered over the body, unlike the central nervous system of other symmetrical animals (Fig. 1). In case of amputations or injury to the peripheral parts, but with intact central part, these animals have the unique property of self-repair to maintain their radial symmetry. This biological process is known as symmetrization (Michael et al. 2015).

Historically, the taxonomic classification of animals was based on their symmetry. For instance, French naturalist Georges Cuvier grouped animals with radial symmetry in the taxon Radiata (Zoophytes) (Cuvier et al. 1834). Today, this taxon is believed to be a polyphyletic group of distinct phyla of the Animalia (Hadzi 1963). Most radially symmetric animals are symmetrical about an axis extending from the center of the oral surface (which contains the mouth) to the center of the opposite, aboral end.

### Different Forms of Radial Symmetry

Radial symmetry can be modified evolutionarily by the arrangement of some paired structures or other combinations around the central axis, which gives rise to some unique forms of radial symmetry. Depending upon the number of axis of symmetry, the radial symmetry can be categorized as follows:

- (a) **Biradial symmetry** (e.g., ctenophores and some anthozoans) due to presence of only

**Radial Symmetry, Fig. 1** Pentaradial symmetry in *Asterias arenicola*. (Taken from Playfair and McMurrich 1896)

two planes of symmetry, i.e. the transverse or tentacular plane through the tentacle sheaths and the vertical sagittal or pharyngeal plane at right angles to the tentacular plane

- (b) **Tetramerous symmetry** (e.g., in most of the jellyfish) due to four canals in radial body plan
- (c) **Pentaradial symmetry** (in all the echinoderms like sea stars, sea urchins, and sea lilies) due to branching of body parts into five distinct compartments
- (d) **Hexamerous symmetry** (e.g., corals and sea anemones of subclass Hexacorallia) due to the arrangement of mesenteries and tentacles in the multiple of six
- (e) **Octamerism symmetry** (in Octocorallia and octopus) due to presence of eight appendages and octameric radial symmetry

### Phylum in Animal Kingdom Showing Radial Symmetry

Phylum Coelenterata or Cnidaria is the only phylum in the animal kingdom, showing a good example of radial symmetry. A few examples of this symmetry are also found in phylum Echinodermata.

### Raffle Principle

Frances Tyler

University of Exeter, Penryn, UK

Within polyandrous mating systems, females mate with multiple males over their lifetimes, sometimes within quick succession. In internally fertilizing species this can lead to the ejaculates of multiple males being simultaneously present within the female's reproductive tract (or in the case of external fertilizers, ejaculates being simultaneously present at the site where eggs have been laid), and therefore competition between the ejaculates to fertilize the female's eggs. This is known as "sperm competition," and is recognized as a major force of sexual selection (Parker 1970). It is thought that the selection pressure of sperm competition combined with the cost of producing sperm has led to the evolution of numerous, small sperm, a phenomenon known as anisogamy.

Parker (1990) compared sperm competition to a "raffle" (lottery); a game of chance in which people buy tickets bearing numbers. All of the tickets are mixed together, and then a small subset is drawn at random. The purchasers of the tickets from this subset win prizes. The more tickets a person buys, the greater their probability of winning. Sperm can be thought of as raffle tickets, and the prizes as fertilization of ova – the more sperm

with which a male inseminates a female, the greater his chance of siring offspring.

In a “fair raffle,” each ticket has an equal chance of winning, and so the number of sperm a male inseminates into a female is directly proportional to his fertilization success. In these cases, there is no loss of sperm by any of the competing males during or after mating, all sperm enter the fertilization set, and are equally likely to be used for fertilization. This can occur when sperm storage organs allow free mixing of sperm, for example, in cricket species (Simmons 1986).

Conversely, in a “loaded raffle” tickets do not all count equally. While a male’s success in fertilizing offspring may still increase with increased investment of sperm, the relationship is not directly proportional. The skew in fertilization success among males may be determined by a number of factors, for example, in certain species females may choose not to uptake (Simmons 1986), or to actively eject (Pizzari and Birkhead 2000), the ejaculate of less favored males. Males may use specialized genitalia to remove competing ejaculates from a female’s reproductive tract (Waage 1979). Sperm may be stored in specialized storage organs within the female reproductive tract. If the physiology of these stores leads to stratified rather than freely mixed storage of sperm (Walker 1980), the order in which sperm enter storage will greatly affect the order in which they leave, thus restricting access to the ova. There may be differences among males in some inherent quality of their sperm, which confer greater success in their ability to traverse and survive the rigors of the female reproductive tract, and to fertilize ova (Snook 2005). Factors such as these mean that, even if a competitor buys copious tickets, they do not necessarily have a better chance of winning the raffle.

## Raiding

Gavin Vance<sup>1</sup> and Todd K. Shackelford<sup>2</sup>

<sup>1</sup>Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Psychology, Oakland University, Rochester, MI, USA

## Synonyms

[Intergroup Violence](#); [Tribal Warfare](#)

## Definition

A sudden, often violent, display of force by members of a group against one or more individuals

from another group, with the goal of inflicting injury, taking resources, or capturing females.

In anthropology and biology, raiding commonly refers to a spontaneous display of force, enacted by one group against a separate group or individual. Raids may be violent, resulting in injury or death for the targeted individuals, and are often biased in favor of the attacking group. The goal of a raid might be to inflict injury or death on members of the target group, to kidnap females or to steal resources such as food.

## Nonhuman Primates

Raiding is present in both chimpanzees and humans, but not in bonobos (Pandit et al. 2016). Watts et al. (2006) provided anecdotal examples of lethal intergroup aggression in chimpanzees and argue that these observations are consistent with an evolved function of lethal, intergroup aggression in chimpanzees. (The proposed fitness benefits of chimpanzee raids include that killing rival group members reduces competition for limited resources). This hypothesis is further supported by Mitani et al.' (2010) study which observed territorial expansion of chimpanzees who fatally wounded rival group members. In an investigation of patrolling behavior (which typically precedes intergroup attacks), Watts and Mitani (2001) observed that chimpanzees who patrolled more frequently and who were more likely to join an existing patrol experience greater mating success. Taken together, the literature on chimpanzee raiding behavior evidences strong empirical support for the fitness benefit of lethal, intergroup aggression.

## Humans

Raiding has also been observed in human tribal societies. In these contexts, tribal warfare is often used interchangeably with raiding and is characterized by highly organized sneak attacks by the men of one tribe against a rival tribe. Often, these raids involve taking resources or capturing women from the rival group; however, raiding may have

reproductive benefits, even when women are not captured and taken as wives. Glowacki and Wrangham (2015) observed that men from a tribe of nomadic pastoralists who participated in more raids during their youth have more wives and children later in life. The authors suggest that, because Nyangatom men trade livestock in exchange for wives, and because raids often involve the taking of livestock, Nyangatom men may enhance their reproductive success as an indirect result of performing raids.

In a meta-analysis comparing patterns of raiding behaviors across species, Manson et al. (1991) noted several similarities and differences between chimpanzees and tribal humans. Manson et al. noted that human and chimpanzee raiding are similar in that intergroup aggression is largely displayed by males, with females rarely taking an active role in the hostilities. The authors suggest that this sex difference may be due to males being the philopatric sex, meaning that, as opposed to females, males do not leave the group into which they are born. As a result, males are unlikely to injure or kill genetically related kin during a raid. The authors also provide evidence that, for humans in particular, raids are likely intended to capture females from rival groups when there are few material resources (e.g., food, land) that can be taken instead. Additionally, Manson and colleagues found that accumulation of material resources was associated with polygyny, which suggests that raiding to take material resources and raiding to kidnap women may both have consequences for men's reproductive success.

Overall, empirical data on raiding in tribal societies of humans suggests that, for them raiding does and for ancestral humans, raiding did generate reproductive benefits. Further, the apparent similarities in raiding behaviors between humans and chimpanzees suggests the possibility that raiding has been a feature of hominid life since the most recent common ancestor between humans and chimpanzees, 5–6 million years ago. Still, further investigation is needed to determine whether raiding in humans is best understood as a phylogenetically conserved behavior whether human raiding might reflect specialized adaptation in humans that is not present in chimpanzees.

## Ralph Miller

Todd Schachtman<sup>1</sup>, Martha E. Escobar<sup>2</sup> and Aaron P. Blaisdell<sup>3</sup>

<sup>1</sup>Psychological Sciences, University of Missouri, Columbia, MO, USA

<sup>2</sup>Department of Psychology, Division of Life Sciences, Oakland University, Rochester, MI, USA

<sup>3</sup>Department of Psychology, University of California, Los Angeles, CA, USA

## Education and Early Influences

Ralph R. Miller (1940–) grew up on the south side of Chicago, near Hyde Park, in the shadow of the University of Chicago, and near a lot of great

bookstores. Miller entered MIT in 1958, and in 1962 he earned a BS in Physics with a thesis titled, “Considerations of Precision Nuclear Spectroscopy Utilizing Fiber Optics Detection Systems.” Miller went on to earn a Master’s degree in High Energy Physics from Rutgers University (1964) with a thesis titled, “An Automated System for the Detection of Elementary Particles.” While at Rutgers, his interests shifted to psychology, and under the supervision of William Pavlik, Miller went on to earn a Master’s degree in Social Psychology from Rutgers (1966) with a thesis titled “No Play: A Means of Conflict Resolution.” While working on his Masters, Miller became interested in the social learning theory of Neal Miller and John Dollard and was greatly influenced by his interactions with those focused on learning and conditioning processes, such as Norman Spear, George Collier, Michel D’Amato, and Carolyn Rovee Collier. With his focus being now the study of learning and memory in rodents and humans, Miller joined the laboratory of Donald Lewis at Rutgers. He went on to earn a Ph.D. in Physiological Psychology (1969) with a thesis titled “Effects of Environmental Complexity on Amnesia Induced by Electroconvulsive Shock,” which investigated amnesia and recovery of memories after amnesic insult. Miller’s work was extremely timely, as there was extensive debate at the time regarding whether amnesia-inducing trauma disrupted memory consolidation or retrieval. In Miller 1973, he published a landmark paper on *Psychological Review* (“Amnesia, consolidation, and retrieval”), which is still considered a citation classic in this area. As a graduate student, Miller was one of the original investigators to observe that cued reactivation of an old memory renders it briefly vulnerable to experimental amnesia (Misanin et al. 1968). Today, that brief window of vulnerability is presumed to represent retrieval-induced destabilization during which memories are labile and subject to change prior to entering a period of “reconsolidation.” Notably, Miller has always strongly disagreed with the “reconsolidation interpretation” of the phenomenon because recovery from the performance deficit induced during the vulnerability period is sometimes observed.

## Academic Career

After obtaining his Ph.D., Miller joined the Psychology Department faculty at Brooklyn College of the City University of New York (1969) and rose through the ranks to become a tenured Associate Professor (1973) and Professor (1978). During this time, he spent a year as a visiting Fellow in Experimental Psychology at the University of Cambridge (Kings College, UK, 1975–1976). In 1979, Miller joined the faculty at the State University of New York at Binghamton (today, Binghamton University), where he has spent the rest of his career. In 2003, Binghamton University awarded him the rank of Distinguished Professor of Psychology. Throughout his academic career, Miller has served as Editor of *Journal of Experimental Psychology: Animal Learning & Cognition* (2014–2019) as well as *Learning & Behavior* (1997–2002). He has also served as President of the Eastern Psychological Association, the Pavlovian Society, and Division 3 of the American Psychological Association. He was named Fulbright Scholar on two occasions. At the time this entry was written, Miller's work had resulted in 345 publications and continuous federal funding for a 43-year period. Since becoming a professor, 22 students earned their Ph.D. and 13 individuals received Postdoctoral training under Miller's supervision.

## Major Contributions to the Study of Animal Cognition and Behavior

Although Miller is arguably one of the most recognized researchers in the field of animal learning, conditioning, and cognition, throughout his career he has made significant contributions to the theoretical and empirical advancement of neuroscience, cognitive processes, social processes, animal behavior, and psychopathology. Much of Miller's work has used Pavlovian associative conditioning procedures with rats; however, he has also made significant contributions using contingency judgment and evaluative conditioning with human participants. Miller's contributions have been significant to the understanding of memory retention through metamorphosis in frogs,

Machiavellianism, causal reasoning in human and nonhuman animals, source monitoring in Korsakoff's syndrome, preference for signaled shock, neophobia, electroconvulsive shock (ECS)-induced amnesia, occasion-setting, treatment of fear of public speaking, associative interference, experimental extinction, fear relapse, artificial intelligence, processing information as a member of a group, altruism and selfishness, opioid analgesia, conditioned inhibition, coding of temporal intervals, tail shock methodology, biological significance, context and habituation, treatment for smoking cessation, infantile amnesia, cue-competition phenomena (e.g., blocking, inhibition, overshadowing, and relative stimulus validity), associative learning as a model of schizophrenia, and adaptive memory.

## The Learning-Performance Distinction

If Miller's work were to be summarized in one sentence, it would be *the systematic investigation of the difference between what has been learned and how that learning is expressed in performance*. His view is that performance (e.g., conditioned responding) does not always reflect what a subject has encoded; thus, there are complex processes that determine whether or not a given environmental situation results in the elicitation of a conditioned response. The learning-performance distinction is a long-standing debate in the history of the study of learning and conditioning. For example, in his classic studies of *latent learning*, Tolman (1948) observed that rats allowed to navigate a maze did not express learning of the layout of the maze until they were under a motivational state that facilitated expression of that learning. That is, what they knew (learning) was not necessarily expressed in their behavior (performance). Another example of the learning-performance distinction is the phenomenon of *spontaneous recovery*, first reported by Pavlov (1927). Pavlov presented dogs with a sound (the conditioned stimulus or CS) that was paired with food (the unconditioned stimulus or US), resulting in a salivation conditioned response when the CS was presented. Repeated presentations of the CS alone resulted in low levels of conditioned responding (extinction). Pavlov observed that

the response recovered without further training if time was allowed to elapse between extinction and assessment. This observation suggested that extinction involves some kind of masking of the acquired CS-US association that remained intact through extinction.

Miller's interest in the learning/performance distinction stems from his work as a graduate student at Rutgers. In a series of seminal studies, Miller and colleagues trained rats with a passive avoidance conditioning procedure followed by ECS. With this treatment, rats showed amnesia for the passive avoidance conditioning experience. If rats received a single "reminder" shock (Miller and Springer 1972a, b) between ECS treatment and assessment, however, the avoidance response was expressed. This showed that the association *was* formed during training and that the amnesia-inducing ECS did not destroy it or keep it from being consolidated and retained; it merely prevented its expression. Indeed, they observed that the memory was formed in 0.5 s or less since the amnestic treatment presumably disrupted all relevant ongoing neural processing in the brain 500 ms after training (Miller et al. 1969). Miller's findings in this area, along with the work of others such as David Riccio, Norman Spear, and Mark Bouton, have helped shape our understanding that many instances in which performance is not consistent with the conditions of training may reflect not a failure to acquire and retain a memory, but a difficulty in retrieval of acquired memories that remain intact even after treatments intended to disrupt them.

### **Acquired Information Expression is Relative to the Situation: The Comparator Hypothesis**

In Miller's view, responding based on an acquired association does not only depend on the strength of the memory of the association, but also on the context in which the memory was acquired and retrieved. According to this view, CS-US pairings will control behavior not only as a direct function of the strength of the CS-US association, but as a relative comparison of the strength of this association and the strength of association between the background cues and the US. These background cues (the environment or "context" as well as

other stimuli that were present in the learning situation) are presumed to serve as "comparator stimuli" for the CS that is being assessed (the "target" CS). The degree to which the target CS produces a conditioned response will be determined by the extent to which the target CS can retrieve the memory of the US (the associative strength of the target CS-US association) *relative* to the extent to which other cues that were present in the situation during learning can retrieve the memory of the US; this latter retrieval of the memory of the US is indirectly triggered by the target CS because presentation of the target CS retrieves a memory of the comparator stimuli, which in turn retrieve a memory of the US. Thus, the comparison is between a memory of the US directly retrieved by the target CS (with a strength that equals that of the associative strength of the CS-US association) and a memory of the US indirectly retrieved by the target CS (with a strength that equals the product of the strength of association between the target CS and its comparator stimuli *and* the comparator stimuli and the US). Hence, if the memory of the US activated directly by the target CS is stronger than that activated indirectly by the target CS, responding will be robust; in contrast, if the memory of the US activated directly by the target CS is weaker than that activated indirectly by the target CS, responding will be attenuated. Thus, failures in performance are expected not because the association between the target CS and the US is weak, but because associations to the comparator stimuli prevent full expression of the CS-US association. Since the mid-1980s, Miller's *Comparator Hypothesis* (cf. Miller and Matzel 1988) has been supported by hundreds of studies and has sparked novel research showing that responding can be modulated through training of the comparator stimuli (e.g., Blaisdell et al. 1999), with new theories being developed to explain these phenomena (for reviews, see Denniston et al. 2001; Stout and Miller 2007). The Comparator Hypothesis has undergone significant evolution since its first formulation, with an extended version, the development of which was prompted by the empirical discovery that overshadowing and latent inhibition treatments mutually counteract

their response-attenuating effects other (Blaisdell et al. 1998), that incorporated rules for dealing with multiple comparator stimuli (ECH; Denniston et al. 2001), and a mathematical formalization of the ECH (Sometimes Competing Retrieval [SOCR]; Stout and Miller 2007).

### Temporal Coding as an Essential Component of the Formation and Expression of Associations

Temporal contiguity (the extent that two events occur in close temporal proximity) was described by Aristotle as one of the basic laws of association between ideas. Not surprisingly, contiguity is essential for the formation of associations between the CS and US; however, sometimes contiguous events (e.g., a CS and US that are presented simultaneously) do not lead to robust behavior. Miller has suggested that the temporal relationship between paired events is encoded as part of the “association” that links their representation in memory. This temporal information includes synchronous versus asynchronous onset, order of presentation, and duration. In this strict contiguity view, an association is formed as long as the two events are presented fairly close together. This temporal information is not just incidental; rather, it is a critical determinant of how the association will later be expressed in behavior. Miller’s *Temporal Coding Hypothesis* (e.g., Arcediano and Miller 2002; Miller and Barnet 1993) incorporates the extent to which the CS predicts the US and how this predictability is modulated by their temporal relationship. The most commonly held view of classical conditioning is that pairings of a CS and a US lead to the CS predicting the US, and that conditioned responding is determined by this predictive relationship; functionally, the CS prepares the subject for the impending occurrence of the US. Various observations support this view: if the CS and US occur simultaneously (simultaneous conditioning) or the US precedes the CS (backward conditioning), little conditioned responding is observed because the CS has little predictive value. According to Miller’s Temporal Coding Hypothesis, however, prediction only determines whether performance, not learning, is to occur. In this view, if the CS and US are presented together, an

association is formed between them. Performance depends on the temporal arrangement of the CS and US and is determined by the extent to which the CS predicts the US. Miller has presented extensive evidence that these latent associations can be uncovered through the use of second-order associations. For example, if a CS1 receives backward pairings with the US (i.e., US-CS1), CS1 elicits little responding (CS1 is not predictive of US occurrence). If a second CS (CS2) is paired with CS1 (CS2-CS1), however, CS2 comes to be predictive of CS1’s occurrence. If CS1 has developed an association to the US, then CS2 should come to elicit a response because CS2 holds a predictive relationship to the time at which US occurrence should be expected. Such integration of multiple experiences with temporal components has been demonstrated in human and non-human subjects (e.g., Arcediano et al. 2003).

### Conclusion

R.R. Miller has been one of the greatest contributors to the advancement of animal learning, memory, and cognition. His theoretical contributions, including the Comparator Hypothesis and Temporal Coding Hypothesis, have not only served to provide a framework of understanding the complex dynamics of acquired behavior, but have sparked novel research and theoretical developments that have advanced our understanding of the complex relationships between what is learned and what is expressed in behavior. Miller’s prolific experimental contributions have spanned multiple fields beyond learning and memory, including social, abnormal, and physiological processes, and have had broad impact beyond psychology. With a career that spans over 50 years, Miller’s work is still considered to be current, with even his graduate student research continues to shape our understanding of learning and memory, such as the reconsolidation debate.

## Randy Thornhill

Randy Thornhill  
University of New Mexico, Albuquerque,  
NM, USA

## Early Life and Educational Background

Thornhill was born on December 7, 1944 in Decatur, Alabama, USA. He obtained a B.S. in Zoology at Auburn University in 1968, an M.S. in Entomology at Auburn in 1970, and a Ph.D. in Zoology at the University of Michigan in 1974. His 633-page Ph.D. dissertation, *The Evolutionary Ecology of the Mecoptera (Insecta)*, reported on his original research on the behavior and ecology of mecopterous insects and included the first study of female mate choice in an animal under field conditions.

## Professional Career

After receiving his Ph.D., Thornhill was a research entomologist for a year in the Department of Entomology and Nematology of the University of Florida in Gainesville, FL. In 1975, he accepted a faculty position in the Department of Biology at The University of New Mexico, Albuquerque, New Mexico, where, as of 2016, he is still on the faculty. His position in 2016 at the University of New Mexico is Distinguished Professor Emeritus. Since 1975 until present, he has taught courses in evolutionary biology, ecology, and animal behavior at The University of New Mexico. He has had temporary appointments with numerous universities, including the University of Helsinki, the University of Colorado, the University of Melbourne, Kyoto University,

Nagoya University, University of Bielefeld, University of Michigan, and Colorado State University.

Thornhill has authored approximately 200 publications, including four research monographs/books. As of 2016, his publications have been cited about 25,000 times.

Thornhill has received various awards for research contributions, including the Senior Distinguished Scientist Award of the Alexander Von Humboldt Foundation, a Guggenheim Fellowship, a Japan Society for Promotion of Science Fellowship, Fellow of the Animal Behavior Society, and Distinguished Entomologist Award from the Department of Entomology, University of Georgia.

Thornhill has served on editorial boards of several scientific journals. He has served as president elect, president, and past president of the Human Behavior and Evolution Society.

## Research Interests

The evolution of human behavior and psychology is the topic of the majority of Thornhill's publications, including three of his books—one with Craig Palmer, *A Natural History of Rape: Biological Bases of Sexual Coercion*, one with Steve Gangestad, *The Evolutionary Biology of Human Female Sexuality*, and one with Corey Fincher, *The Parasite-stress Theory of Values and Sociality: Infectious Disease, History and Human Values Worldwide*. Judging from the citation record of his papers and books, his research has contributed to a range of disciplines, including ecology, evolutionary ecology, behavioral ecology, evolutionary biology, entomology, ornithology, and human psychology and behavior. His main interest continues to be sexual selection processes, especially female choice.

## Rational Imitation

Ildikó Király and Katalin Oláh  
Eötvös Loránd University, Budapest, Hungary

## Definitions

### Imitation

Imitation is a behavior where an individual observes a conspecific's (or even an individual's

belonging to another species) movements or actions and consequently replicates it. This copying behavior – be it blind or insightful with respect to understanding of means-end relations of the action – occurs in most of the cases for novel behavior, previously unknown to or out of the repertoire of the observer (cf. Want and Harris 2002; and see also Call et al. 2005, for alternative definitions on imitation). As such, imitation is seen as a tool for learning novel behavior, that is, as a form of social learning that can lead to the transfer of information between individuals and also between groups of people. This form of information transfer allows the transmission of behaviors, such as tool use, customs, and rituals as well – behavioral patterns that are generally considered as cultural knowledge (Boyd and Richerson 1985). Though imitation as a process is accepted as an important tool of information transfer in social sciences in general, the nature of this skill is still disputed – whether it is a conscious cognitive mechanism or a basic low-level mechanism (Gergely et al. 2002; Paulus et al. 2011a).

### Rational(ity)

The principle of rationality was introduced as a fundamental factor governing action selection on the bases of background knowledge. According to Newell (1982) “if an agent has knowledge that one of its actions will lead to one of its goals, then the agent will select that action” (p. 102). In that sense, rationality is an inferential principle-guiding selection of behavior in accordance with one's knowledge: humans will choose actions to execute that seem the best option based on the knowledge the individual possesses. The rationality principle has also been proposed to be the central inferential principle for humans' – even infants' – action interpretation mechanism (Gergely and Csibra 2003): humans interpret behavior in terms of actions executed to attain goals as efficiently as possible in a given environment.

### Rational Imitation

Rational imitation refers to the phenomenon that agents apply the *rationality principle* in the process

of social learning: they take into account the efficiency of observed actions to achieve a specific goal or outcome when deciding whether to reenact a specific behavior or not, in other words whether to imitate or not. The approach of rational imitation as a selection process presupposes imitation to be a conscious, inference-based, insightful mechanism (Gergely et al. 2002).

## Introduction

Rational imitation as a theoretical construct emerged from experimental research. In this entry, therefore, the phenomenon and relatedly the formation of its explanations will be introduced through empirical examples.

### The Birth of Rational Imitation

The principle of rationality has been introduced as an inferential principle to the cognitive machinery as a component of humans' so-called teleological action interpretation mechanism. The teleological action interpretation system – teleological reasoning – relates three aspects of action interpretation in a systematic manner by the assumption of rationality: *goals, actions, and situational constraints*. Given information about any two of the three elements, one can infer and predict what the third element ought to be if the agent behaves in a rational manner (see Csibra et al. 2003). Within this frame, teleological reasoning operates with the help of two main assumptions: (a) actions serve to bring about future goal states and (b) goal states are realized by the most efficient action available to the actor within the constraints of the situation (Gergely and Csibra 2003).

Empirical evidence supports that already young human infants (henceforth “infants”) – from the age of 6 months – are able to use the above naïve theory of rational action: they represent actions as efficient means to bring about specific goal states in the world, so teleological action interpretation is supposed to be a core, early available mechanism (Gergely and Csibra 2003). This naïve theory for action interpretation, capacity to infer rational, goal-directed action, has

been shown to be part of the cognitive machinery of nonhuman primates as well (Wood and Hauser 2008).

Interestingly, the availability of teleological reasoning has been demonstrated only for action perception and understanding, both in human infants and nonhuman primates. Indeed, if teleological reasoning as a naïve theory is available already for infants, and based on this, they expect agents to act rationally, it is reasonable to assume that infants themselves would also rely on the same principle of rationality to guide their own choices of instrumental actions. This prediction, however, was apparently contradicted by the results of *imitation studies*. As an illustrative example, in Meltzoff's (1988) seminal imitation study, 14-month-old infants chose to reenact a model's unusual and sub-efficient action: after infants witnessed a model use their head to illuminate a light box instead of just using their hands to induce the same effect, most of the children chose to perform the same unusual action when given the opportunity to operate the box. Such a behavior is difficult to interpret as the rationality principle would dictate to choose a solution that leads to the goal state with the least amount of effort – in this case, operating the light box by touching it with one's hand seems more efficient (and hence more rational) than bending forward from the waist to use one's forehead to achieve the same end.

In order to test whether imitation as a form of learning also exploits the naïve theory of rational action, Gergely et al. (2002) developed a modified version of Meltzoff's (1988) imitation paradigm. The aim of the study was to investigate whether efficiency evaluations could modify infants' action choice and production. In the example study of Meltzoff, infants watched an adult place her hands on the table and then use an unusual action to illuminate a light box: she bent over and pressed the box with her forehead. Note that the model's hands were obviously free and she could have easily used them to achieve the goal. In addition to this original version, a new context condition was introduced in which the demonstrator's hands were occupied when she performed the unfamiliar head action to operate the touch

lamp (hands-occupied condition): infants were shown the adult performing the same unusual action but with the difference that her hands were unavailable during the demonstration (she was holding a blanket around her shoulders). In this hands-occupied condition, thus, the situational constraints *justified* the use of the novel means, while this was not true for the original (hands-free) condition. When these infants were given the chance to play with the box a week later, in the hands-free condition, most of them (69%) also used their head to illuminate the light, replicating Meltzoff's results. However, in the hands-occupied condition, only a small proportion of infants (21%) later used their head to illuminate the light box; the majority of them just used the more normal (but undemonstrated) method of pressing the box with their hands.

Gergely et al. (2002) referred to this phenomenon as *rational imitation*, which is a context-sensitive, selective learning mechanism of novel means actions. In a situation where the contextual constraints justified the use of a non-efficient novel means, infants did not imitate it but turned to a familiar action: manipulating the box with their hand. However, high-fidelity imitation – that is, performing the novel means – was induced when goal attainment was realized intentionally by the novel means despite the obvious availability of the most efficient action to the actor within the constraints of the situation.

### Replications

Since the original demonstration, the finding of selective rational imitation has been replicated several times and shown to generalize across a range of different task contexts with 12- and 14-month-old infants.

In a close replication attempt, Zmyj et al. (2009) investigated whether 9- and 12-month-olds detect voluntary as well as nonvoluntary constraints in the head-touch task. In this study, infants watched *video sequences*, which displayed a person illuminating a lamp using the head. The hands of the model were either free (like in the hands-free condition above), or occupied by voluntarily holding a blanket (like in the hands-occupied condition above), or non-voluntarily

restrained by being tied to the table. This study yielded further evidence for rational imitation in 12-month-old infants who chose to use their hand but only in the condition where the model's hands were tied down. Nine-month-olds did not differentiate between the conditions. Thus, these results suggest that by 12 months of age, infants can take into account constraints that the actors do not have the power to change when interpreting behavior and choosing a learning strategy. Yet, comparing the results with those of the original study, it seems that it is not until the age of 14 months that children also consider constraints that are deliberately chosen.

Among the conceptual replications, Schwier et al. (2006) developed a different new task and investigated whether 12-month-olds understand that actors choose action plans rationally based on an assessment of current reality. In this study, infants were presented with a toy house and a toy dog. During the demonstration, an adult took the dog and made it enter the house by going down the chimney. In the condition that was analogous to the hands-occupied condition in the original study (see above), the demonstrator first attempted to use the door instead of the chimney, but as it turned out, it was locked, which justified the use of the chimney as an entrance. In the other condition (analogous to the hands-free condition, see above), the door was visibly open but the demonstrator voluntarily chose the chimney. In both conditions, the door was always open during infants' turn to manipulate the toys. Infants made the dog enter the house through the door more often in the condition in which the door was closed during the demonstration, arguably because the use of the chimney could be attributed to the door being locked. On the other hand, in the condition in which the door was open during the demonstration, infants faithfully imitated the unusual action of putting the dog through the chimney. These results highlight that young children not only learn how to attain goals in the form of imitation but also how to plan the attainment of the goal in the given situation.

The pattern of selective imitation was also shown for complex tool-use behavior (Király 2009). In the experimental condition of this

study, the model first demonstrated that the hand is not efficient to attain a given goal (to take a little box out of a bigger one) and then used a novel tool (a string with a magnet) successfully. In the other condition, only the tool-use action was demonstrated. Infants were more likely to reenact the demonstrated rather complex tool-use procedure to attain the goal when they were shown negative evidence with respect to the efficiency of the hand action (93%), than in the condition where only the tool-use behavior itself was shown (54% attempted tool use). Infants inhibited their prepotent response, the hand action, when the demonstration highlighted and justified the use and efficiency of the novel means.

The above-introduced studies are examples of a growing body of research that revealed the capability of preverbal infants to imitate selectively; however, the flexibility of this capacity has only been recently targeted. The objective of the study of Gellén and Buttelmann (2017) was to test whether 14-month-old infants can flexibly alternate between faithful copying and introducing novel solutions in an imitation paradigm. Participants were presented with two novel actions in a sequence. In one of the situations, the model illuminated a light box; in the other situation, she turned on a sound box. The model alternated the way of attaining her goal in these situations, either she used her forehead (head touch) or sat on the apparatus (sit touch). Importantly, each participant observed one of these actions where the model's hands were occupied, while during the demonstration of the other, the model's hands were free. The results revealed more faithful imitation when no physical constraint provided justification for the unusual action. The study also provided evidence that preverbal infants can adapt their behavior to the changing circumstances. These results point to the flexible, adaptive nature of action interpretation and imitative behavior on an individual level.

Action interpretation with the help of the rationality principle seems to guide the selection of the to-be-learned novel action sequences, at least in the case of human infants. The question is: is this capability present in other species as well?

## The Evolution of Rational Imitation: Evidence in Nonhuman Animals

The phenomenon of rational imitation highlights that infants' action interpretation takes into consideration the situational constraints and relatedly the supposed adaptability of action choice in order to attain a certain goal.

In order to investigate whether rational imitation as a competence is specific to humans or not, Buttelmann et al. (2007) tested enculturated chimpanzees (*Pan troglodytes*) with a paradigm following closely the procedure of Gergely et al.' (2002). Chimpanzees watched a human demonstrator act on six different apparatuses, showing how to operate them using an unusual body part (e.g., by pressing it with foot). Like in the original study, participants were either tested in a hands-free or a hands-occupied condition. The results of the study revealed that like human infants, chimpanzees imitated the modeled action more often in the hands-free than in the hands-occupied condition. Thus, enculturated chimpanzees, who could have profited from the gradual acquisition of behavioral expectations revealed and reinforced by human keepers raising them, seem to have some understanding of the rational planning and execution of others' intentional actions.

However, it is an open question whether this intention reading capacity is only present in enculturated individuals or it is part of apes' cognitive capacity repertoire in general. The above-modified paradigm of Buttelmann, Carpenter, Call, and Tomasello was tested with chimpanzees, orangutans, gorillas, and bonobos and also with a comparison group of 14-month-olds (Buttelmann et al. 2008). While infants used a tool more often when a demonstrator freely chose to use it, in contrast to situations when she was forced to use it, among the ape species, orangutans were the only ones that showed this pattern.

Range et al. (2007) showed an analog capacity in the domestic dog. In their experiment, subjects watched as a demonstrator dog used her paw to pull a rod closer instead of taking it into her mouth (which would be more natural to the species). In the first group, the demonstrator dog was holding a ball in her mouth, thereby providing a justification for the paw action. In the second group,

however, no such constraint was visible. In the first trial after observation, dogs only imitated the unusual means if the demonstrator dog had been carrying a ball in her mouth during the modeling of the behavior. Consequently, domestic dogs, like children, demonstrated inferential selective imitation. However, this finding has been criticized by Kaminski et al. (2011), since the results of their replication attempt suggest that dogs do not distinguish rational from irrational acts and instead simply show a capability of monitoring humans and “predicting” their behavior on the basis of past experience or to follow certain communicative commands.

Overall, the above results suggest that among animal species, only some apes (orangutans) show clearly an understanding of the rationality principle.

### **Challenges and Reconsiderations: Problems with the Original Interpretation of the Rational Imitation Phenomenon**

The explanation of rational imitation as a context-sensitive and selective reenactment of novel actions has been challenged on several grounds. Both alternative interpretations described below were raised based on empirical data questioning the inferential nature of the phenomenon and theoretical challenges brought a need for theory refinement.

#### **The Dispute on Rational Imitation as an Inference-Based Process**

In their alternative account, Paulus et al. (2011a, b) suggested that the phenomenon is rather attributable to a low-level copying process, and it is not inferential. In their view, imitation – rather than being rational – emerges due to the interaction between an automatic motor resonance elicited by the observed actions and the limited motor capabilities of infants. Automatic motor resonance means that observing the behavior of another individual evokes similar brain activity in the observer to what is necessary to bring about the action in reality. The motor resonance

account thus claims that young children show less imitation in the hands-occupied condition because the observed action is not part of their motor repertoire, whereas the one performed in the hands-free condition is. This is due to the fact that in the latter case, the hands of the demonstrator rest on the table and thus provide support for the bending actions, whereas in the hands-occupied condition, the hands provide no such support.

Modifying the paradigm by varying whether the actions in the hands-free and hands-occupied conditions are realized with leaning on the table seems to have an impact on the results. For example, when the model’s hands were occupied by two foam balls on the table, infants imitated the head action arguably because the hands resting on the table (on top of the balls) provided support and thus evoked motor resonance despite the fact they were actually used for a different purpose.

The underlying supportive mechanism of action selection and the role of context in action understanding have been studied in human adults by functional brain imaging. In the study of Brass et al. (2007), participants observed an unusual action in non-justificatory or implausible (pushing a button by elbow while the hands are free) versus justificatory or plausible contexts (pushing a button by elbow while the hands are occupied with holding books). The results of this study showed that those brain areas that are part of a network involved in inferential interpretive processes of rationalization and reasoning about the mental states of others are found to be distinctively active when the action occurs in an implausible context. However, no differential activation was found in the primary motor and mirror network, so in regions that are supposed to be active in blind imitative contexts. These findings support the assumption that action understanding and preparation to act in novel situations is primarily mediated by an inferential interpretive system, involving rationalization induced by contextual factors, rather than simply by the motor mirror system.

With respect to the competences of infants, importantly, the motor resonance model can explain the findings of the original head-touch

paradigm but cannot account for selective imitation in the conceptual replication paradigms (see also above in section “[Replications](#),” Schwier et al. 2006; Király 2009) where the demonstrated actions are identical, and thus the induced motor resonance should be equal, and consequently no difference in imitative behavior is predicted by the motor resonance account.

Another contrasting view was proposed by Beisert et al. (2012), who argued that the selectivity of infants’ action imitations is due to differences in attentional factors. According to their account, the head action receives less attention in the hands-occupied condition – in contrast to the hands-free context – as the hidden hands are unusual and therefore more salient and attract more attention.

The validity of this perceptual distraction model has been tested with the help of tracking gaze directions – as a cue for attention focus – in infants and adults as well (Buttelmann et al. 2017). The looking behavior was analyzed when participants observed the head-touch demonstration in the two original (hands-free and hands-occupied) conditions. The results of the eye-tracking data do not support the perceptual distraction account: both infants and adults predominantly observed the relevant head action in each condition. The amount of looking at the modeled head-touch action did not statistically differ in the empirical conditions. Consequently, infants and adults do not seem to attend differently to constrained and unconstrained modeled actions.

Overall, the suggested alternative accounts questioned the inferential interpretation of the phenomenon of selective imitation based on empirical data, yet their approach cannot fully account for the controversial findings in the field.

### **Challenges for Rational Imitation as a Coherent Theoretical Construct**

The description of rational imitation emphasized that action interpretation emerges from the observation of the overt behavior within a given context: in the head-touch procedure, when the experimenter’s hands were occupied, touching the light with her head was the only available means for turning on the light, so its use was

justified. Consequently, based on the observation of behavior and context, infants could have interpreted her head touch as not essential to accomplishing her goal. Infants thus used their hands to light up the lamp. But one might raise the question of why the majority of infants reenacted the novel head action in the hands-free condition? Here both the model’s and infant’s own hands were free, so infants could have (rationally) opted for accomplishing the goal by performing the more efficient “hand action.” A possible interpretation would be that in this situation, where the experimenter’s hands were free, and she could have used her hand to turn on the light, infants may have made the inference that using her head was indeed essential to accomplishing her goal.

However, this apparently paradoxical behavior highlights the need for a broader explanation framework that goes beyond the rationality account. These accounts build on infants’ proneness to interpret action demonstrations as social communication. Let us revisit from this angle the rational imitation proposal (Gergely et al. 2002; and see also Buttelmann et al. 2008 for a similar argument) which suggests that the reproduction of this apparently irrational action reflected infants’ interpretation that using the novel head action was possibly essential to attain the goal, so the novel action was a manifestation of some unknown reason that must justify the action as rational. The imitation of this new head action can be seen as a way of learning what the agent’s (rational) reason for his action might have been. The main problem with this proposal is that it essentially makes the idea of appealing to the rationality principle unfalsifiable; when infants did not reproduce the demonstrated action (in the hands-occupied condition), it was treated as evidence of the application of the rationality principle, and when they did reproduce it (in the hands-free condition), it was also interpreted as evidence for the operation of the same inference. Overall, the original explanation of selective head-touch imitation purely in terms of the application of the rationality principle fails to capture all of the relevant aspects of the selective imitation phenomenon.

## Introducing a New Approach to the Selective Imitation

A new approach to the selective imitation phenomenon attempts to explain not only why infants refrained from imitating the novel action when it seemed rational but also why they reproduced it when it was obviously not efficient. Király et al. (2013) proposed that this strange behavior is explained by infants' interpretation of action demonstrations as communicative manifestations of novel and culturally relevant means actions to be acquired. According to this theoretical framework, in their endeavor to master the often arbitrary customs of a given society, young children are prepared to learn behaviors of which the function is not apparent at first glance. In doing this, in the absence of the possibility to apply the rationality principle, they rely on the communicative signals of experienced others. Király and colleagues found that 14-month-olds reenacted the novel arbitrary means action, the head touch, only following a communicative demonstration, and not in an incidental observation context. Additionally, results revealed that infants' tendency to reproduce communicatively manifested novel actions is restricted to behaviors where the model obviously accomplished a change of state in the environment, so the goal could have been identified, and infants could construe goal-directed instrumental act.

In details, (following the argument of Király et al. 2013) because of the communicative signals that accompany the action demonstration, infants construe of it as a communicative action rather than a purely instrumental action (Csibra and Gergely 2011; Gergely and Jacob 2012). They take the situation as a teaching context where the demonstrated action and the communicative context together make them learn a functional action. In the hands-occupied condition, the rationality principle is sufficient to form a coherent interpretation of the situation; however, this is not the case in the hands-free condition. Thus, observers will search for alternative explanations. The communicative nature of the demonstration will induce the expectation that there is some relevance of the specific behavior presented. Because of this, besides construing of the final goal as "lighting

the lamp," infants will also construe of a subgoal, which is to achieve this by making contact between the lamp and their forehead. Rationality is interpreted in terms of this subgoal: if the goal is to touch the lamp with the forehead, then the demonstrated action no longer violates the rationality principle. Since the function of this subgoal is not apparent, but the demonstrator has expressed the intention to pass this behavior on, the action itself will be interpreted as normative.

## Conclusions

The phenomenon of selective imitation highlights that humans, and in some cases other species as well, do expect to learn from actions performed communicatively. In that angle, they are rational in the evolutionary sense; they learn efficiently from their environment observing and analyzing the attempts of their conspecifics. Nevertheless, as the current results indicate, the mechanisms of such learning cannot be explained solely by reliance on the principle of rationality of instrumental actions alone.

## Definitions

### Rational

To be *rational* means to reason based on logic (see [Logic](#)). This definition of rationality is agnostic with respect to physical mechanism, and as a result allows for descriptions of both biological organisms and computing machines as being rational, if their behavior is governed by logic. For an excellent discussion of reasoning in both humans and animals, see the edited volumes by Hurley and Nudds (2006) and Watanabe et al. (2009) from which this work heavily draws. Rational behavior can also be considered to be *optimal* or *ideal*. The behavior of a living organism can therefore be compared to a model designed according to principles of rationality, such as optimal foraging theory (Stephens and Krebs 1986), ideal observer models of perception (Liu et al. 1995), rational accounts of causality (Cheng 1997; Waldmann et al. 2006, 2008), and Bayesian approaches to decision-making (Holyoak and Cheng 2011; Lu et al. 2008; Oaksford and Chater 2007). The remainder of this entry will focus exclusively on psychological rationality (i.e., reasoning and logic) and not rationality by functional rationality.

### Logic

*Logic* describes the rules or principles by which a conclusion is validly derived from its premises.

A logical inference involves the use of logical rules or principles by which a conclusion is validly derived from premises. A hallmark of a logical inference is that it allows new knowledge to be inferred rather than acquired through direct experience (Watanabe and Huber 2006).

### Top-Down

Rational processes are often characterized as being top-down, in contrast to bottom-up processes such as associative learning and conditioning. Top-down processes are rational because they involve the individual going beyond prior experience to derive knowledge or base decisions on the principles of logic. Some examples to be covered below involve rats or pigeons making inferences about the temporal, spatial, or causal relations between events that had never been directly experienced together. These types of inference can be derived from coherent and connected representations (aka cognitive maps, Blaisdell 2009; Tolman 1948) that integrate prior direct experiences, such as prior learning of an A–B and a B–C relationship. The integrated A–B–C map provides the structure upon which A–C relationships may be logically computed (further details below).

Related to the concept of top-down processing is the concept of an informational approach to learning and behavior. These approaches range from early work conceptualizing animal behavior as hypothesis testing (Krechevsky 1932), to recent accounts in terms of propositional knowledge (De Houwer 2009) and information theory (Gallistel and Gibbon 2000; Gallistel et al. 2001).

### Reasoning

*Reasoning* is the process of behaving following principles of logic and rationality. Most descriptions and discussions of reasoning involve behavior that goes “beyond the information given” (Waldmann et al. 2006), in that the behavior was not previously directly learned through principles of reinforcement or reward, nor through other means of direct experience or observation, but instead through an extrapolation beyond the scope of prior learning.

## Categories of Rationality

The following section catalogs the types of reasoning processes that reflect rationality in animals. Many of these concepts are derived from their use in the study of human rationality and reasoning and are necessarily anthropocentric in their origin. Nevertheless, there is no *a priori* basis for defining rationality as a strictly human behavioral trait, and the origins of many human-type cognitive processes often have deep evolutionary roots. Thus, homologous, or at least analogous, reasoning processes that lend themselves to rational analysis can be found in nonhuman animals (Blaisdell 2016).

### Logical or Deductive Inference

The following section presents the six most common types of deductive logical inferences studied in animals. Such inferences are also called *deductive* because the conclusion is deduced from its premises. For example, if all swans are white, and you are told there is a swan in the pond, you can deduce that it is white (cf. *inductive* inference in section [Induction](#)).

### Stimulus Equivalence

Equivalence is a property that defines the relationship between stimuli. Stimulus equivalence was originally defined by Sidman (1990) and involves three types of relations between three stimuli (A, B, and C) that have appeared together in pairwise fashion (i.e., AB, and BC), such as during operant or Pavlovian conditioning, or through mere exposure. These relations are *reflexivity*, *symmetry*, and *transitivity*. In an operant matching procedure, for example, if the subject is reinforced for choosing B after A and C after B, called A–B and B–C matching, respectively, subjects will often match each stimulus to itself (A–A matching), which is called reflexivity. If subjects do the reverse of what was explicitly learned, choosing B after A or C after B, this is called symmetry. Finally, if the subject matches C to A, despite C and A never having appeared together before, this is called transitivity. Urcuioli (2008) has provided a theoretical account for these types of matching behavior in pigeons (see also Urcuioli 2015). Equivalence

learning is thought to serve as the basis for equivalence class formation, by which multiple stimuli are grouped into the same category through sharing a common outcome or an equivalence relationship (Honey and Hall 1989).

The stimulus relation of transitivity deserves special mention due to its role in studying logical deductive inference in animals. A transitive relation need not involve equivalence. Rather, a transitive relationship could involve the ordinal relations between sets of paired stimuli. For example, when presented a choice between A and B, if choosing A but not B is always rewarded, and when presented with a choice between B and C, if choosing B but not C is always rewarded, then, when faced with a novel choice between A and C, a transitive inference would involve the choice of A over C. While A and C never had a history of comparison or differential reward with respect to each other directly, a transitive relationship of  $A > B > C$  would result in a logical deduction that, if  $A > B$  and  $B > C$ , therefore  $A > C$ . This would be a highly useful behavior for an individual living in a social group with a dominance hierarchy. For example, if Individual C has previously observed Individual A always (or usually) win in competitions for a resource (food, mating opportunities, etc.) against Individual B, and Individual B always (or usually) win in competitions with the observing Individual C, Individual C would benefit from inferring that it would also lose in competition with Individual A despite having no previous competitive experience with A. This inference could certainly save Individual C the danger (or embarrassment) of losing a competition.

There has been much debate over the psychological mechanisms that underlie the transitive inference. While some have claimed evidence for a representational account in terms of encoding ordinal relations between stimuli (Bunsey and Eichenbaum 1996), others have found support for simpler associative accounts based on concepts such as value transfer (Frank et al. 2003; Zentall et al. 1996).

#### Spatial Deductive Inferences

Deductive inferences have been shown in the spatial domain. Perhaps the most primitive type

of spatial inference is *dead reckoning* (short for deductive reckoning). Dead reckoning is the process of calculating one's current position by using a previously determined position and advancing that position based upon a known or estimated rate of movement through space over elapsed time. Many vertebrate and invertebrate species show evidence of using a *path integration* process to navigate by dead reckoning (Collett et al. 1998; Etienne et al. 1986). After making an outward journey from a home nest, with many twists and turns, the animal is able to navigate in more or less a direct line back to the home nest after encountering a food item. The spatial vector encoding the distance and direction from the animal's current location to its home nest is computed by integrating each segment of the journey and computing a vector between the current location and the starting point (home nest).

A second kind of deductive inference involves the calculation of the allocentric spatial relationship, or vector, between two external points in space that have never previously been observed together, nor for which the animal has traveled directly from one to the other. According to the spatial integration hypothesis of *cognitive map* formation (Blaisdell 2009), complex spatial representations can be built by linking together simpler representations that share common elements. A spatial representation containing three events (A, B, and C) can be built in one of two ways. On the one hand, all three events could be presented simultaneously, in which case the animal could construct a spatial representation containing all three elements. For example, presenting landmarks (LMs) A and B together with a food goal could establish a spatial map containing all three elements. On the other hand, the same three-element spatial map could be constructed in a piecemeal fashion by joining together two simpler representations, each containing two of the three elements. This process would allow subjects to construct the same three-element map without experiencing all three elements at the same time. An integrated map allows the subject to compute novel relationships among map elements beyond direct experience; a hallmark of the cognitive map.

In Phase 1 of an experiment with pigeons (Sawa et al. 2005; see also Blaisdell and Cook 2005a), subjects received presentations of two visual landmarks consisting of colored geometric shapes (A and B) on a touchscreen in an operant chamber in Phase 1. The screen location of the pair of landmarks varied across trials, but they always bore the same spatial relationship to each other. Pigeons then received training in Phase 2 consisting of  $A \rightarrow \text{Goal}$  pairings. The screen location of the goal was randomly determined from trial to trial. LM A maintained a stable spatial relationship to the goal, thereby signaling the goal location. After pigeons were reliably finding the goal in the presence of LM A, they received nonreinforced test trials with LM B alone. If pigeons had acquired the  $B \rightarrow A$  map during Phase 1 and the  $A \rightarrow \text{Goal}$  map during Phase 2, then they would be able to compute the  $B \rightarrow \text{Goal}$  spatial relationship or map. Evidence for the  $B \rightarrow \text{Goal}$  spatial inference was found in the highest density of screen pecks being clustered at the inferred Goal location. Similar findings have been reported by Chamizo et al. 2006 and Leising et al. 2012.

#### Temporal Deductive Inferences

There is an equivalent type of inference in the temporal domain as to that involving spatial integration. According to the temporal coding hypothesis (Arcediano et al. 2003; Savastano and Miller 1998), the subject forms temporal maps between events experienced such as during a Pavlovian or instrumental conditioning procedure. Moreover, separately acquired temporal maps can be superimposed when they contain common elements, thereby forming an integrated map. This integrated map can be used to compute temporal relationships between events that had never been physically paired. Temporal integration has been shown using a variety of Pavlovian tasks such as second-order conditioning and sensory preconditioning (Barnet et al. 1997; Leising et al. 2007). In second-order conditioning, the CS1-US association is learned prior to the CS2-CS1 association. In sensory preconditioning, the CS2-CS1 association is learned prior to the CS1-US association.

#### Causal Deductive Inferences

Similar to cognitive maps involving spatial and temporal information, causal information can be encoded as a cognitive map. Such causal-based cognitive maps are typically referred to as causal models (Griffiths and Tenenbaum 2009; Waldmann et al. 2006). Once formed, a causal model can be used to deduce cause-effect relationships that have not previously been observed or experienced. One special type of causal inference involves the distinction between observing versus intervening on an effect (Sloman and Lagnado 2005; Waldmann and Hagmayer 2005). For example, observing that the window outside is wet might lead to the diagnostic inference that it has recently rained, which would be a cause for alarm to someone who hung up the wash to dry outside. On the other hand, if the individual knew that they had just watered the garden and that therefore they had caused the window to get wet, they would discount the plausibility of it having recently rained and would therefore not be worried about the state of their laundry. Some evidence that animals can similarly make different causal inferences when presented with an effect that they merely observe versus with an effect that resulted from their own intervention comes from experiments in rats (Blaisdell et al. 2006). Rats in a conditioning chamber first observed a light followed by a tone ( $\text{Light} \rightarrow \text{Tone}$ ). Next, they observe the same light followed by presentations of a food reward ( $\text{Light} \rightarrow \text{Food}$ ). If the rat forms a causal map between each pair of events, then they should form a causal model consisting of light as a common cause of both tone and food. Causal model theory would then make specific predictions about what inferences about food the rat should make when the rat hears the tone at test. If the rat merely observes the tone, then the rat should diagnostically reason that the light must have occurred, and therefore should make the predictive inference that food should also be present. In this case, the rat should look in the feeder for food. If, on the other hand, the tone only occurred whenever the rat pressed a new lever that was placed in the chamber for the first time in the test session, the rat should infer that it, and not the light, had caused the tone, and therefore

should not diagnostically infer the presence of the light. Because the rat does not expect that the light had just occurred, then it also should not expect food, which is an effect of the light (and not the tone or the lever). In this case, the rat should not look in the feeder. This was indeed what has been found in a number of experiments (Blaisdell 2016; Blaisdell et al. 2006; Blaisdell and Waldmann 2012; Leising et al. 2008).

### Inference by Exclusion

Another type of decision-making that can occur under conditions of ambiguity involves inference by exclusion. Oftentimes, an individual is faced with the prospect of making a choice when the correct option that was available in the past is not immediately apparent. In these situations, evidence of absence can signal the likely correct choice. This is called *inference by exclusion*. A simple example of an inference by exclusion is the popular childhood game of asking “In which hand am I holding it?”, where “it” is some small item – such as a coin – that can be enclosed in the hand without revealing its presence. If the decider chooses a hand and the questioner opens their hand to reveal an empty palm, the decider infers that the item must, by logical exclusion, be in the other hand.

Variations on this child’s game have been used as a procedure to study inference by exclusion in animals. At its most advanced level, it is of interest because human children likely learn the meaning of many words by way of an inference by exclusion – a form of word learning termed *fast mapping*. Inference by exclusion has been found in a variety of nonhuman animals, including dolphins (Herman et al. 1984), dogs (Kaminski et al. 2004), and rats (Blaisdell 2016), though the evidence for pigeons has been mixed (Aust et al. 2008; Lauffer et al. 2017).

### Inference in Ambiguous Situations

Because they typically involve drawing an inference beyond prior direct experience or the information previously given, rational inferences are useful when information about a relevant aspect of the world is obscured from perception. Such situations create ambiguity about which of many

possible states of the world is currently present. If a decision to respond or not respond depends on knowing about which of the two (or more) states the world is currently in, the individual may have to make an inference about the true state of the world. Recent experiments that investigate how rats deal with ambiguous states of the world during decision-making utilize a technique by which possible world states are first learned, and then at test, information about a cue necessary to discriminate between states is withheld (Blaisdell et al. 2009). For example, a rat may first be trained to make an instrumental discrimination based on a set of visual discriminative stimuli. After learning the visual discrimination, one of the visual cues, such as a light, can be covered by an opaque metal shield. Thus, the state of the light is ambiguous; it may be on or it may be off. There is no way for the rat to be certain. The rat might act as if it reasons that the light could be on, despite not being able to see it. If this is the case, the rat might base its response by entertaining the possibility that the light, though covered, is actually on. Variations of this procedure have provided evidence that rats indeed are able to make hypothetical inferences about which are the likely states of the world under ambiguous conditions (Fast and Blaisdell 2011; Fast et al. 2016a; Waldmann et al. 2012), and this ability seems to be dependent on a functioning hippocampus (Fast et al. 2016b).

### Induction

An inductive inference involves inducing a general rule, principle, or property by extrapolation from prior examples and evidence. For example, if you’ve seen hundreds of swans during your lifetime, and all of them were white, you might draw the inductive inference that all swans are white (cf. *deductive* inference in section [Logical or Deductive Inference](#)). Inductive inferences are generally more difficult to make given the uncertainty in (a) the accumulated evidence, and (b) the scope of the inference. For example, how many white swans must one observe before one can be certain to draw the inductive inference that all swans are white? And how broadly can you generalize this inductive inference, to all swans in England, all swans in Europe, all swans in the

world, all water fowl closely related to swans, etc.? Furthermore, it only takes one counterexample (e.g., a black swan) to completely undermine the inductive inference. Even for humans, such black swan events can show the fragility of relying too heavily on inductive reasoning (Taleb 1997, 2012).

#### Causal Power

The topic of deductive causal inference has been discussed. Such deductions may require the acquisition of causal representations. Cause-Effect relationships cannot be directly observed, nevertheless, they may be induced through observation of the statistical and temporal relationships between events (Young 1995). Models that account for causal induction include causal model theory (Waldmann et al. 2006), models of causal power (Cheng 1997), and causal Bayes nets (Gopnik et al. 2004; Griffiths and Tenenbaum 2009). Indirect evidence for causal induction in animals comes from the same rat experiments that were used to study deductive inferences from causal maps (Blaisdell et al. 2006). When a rat makes different deductive inferences about the likely presence or absence of food based on whether it had intervened to cause a tone or the tone was merely observed in the absence of an intervention, this implies that the rat had represented the light-tone and light-food relationships as causal, and not merely associative. That is, the rat must have formed a causal model linking light as a common cause of both tone and food. If these relationships were merely associative, then the rat should have expected food every time it heard the tone at test, regardless of whether the tone was merely observed or the result of the rat's intervention (see Leising et al. 2008, for further analysis of the special role of causal agency in deductive causal inferences).

A more direct test for causal induction in the rat comes from a study by Polack et al. (2013). Rats first learned to press a lever for water reinforcement. They then learned that lever pressing produced a tone. Following this, some rats learned that the tone is followed by a footshock (importantly, the levers were not present in the chamber during this training). At test, the thirsty

rats were placed in the chamber with free access to the lever (that had previously earned water when pressed). Rats for which the tone had previously been followed by shock made significantly fewer lever presses than did rats for which the tone had not been paired with shock. If the pairings between tone and shock had established merely a tone-shock association, then the rats should not avoid pressing the lever (for water) because, even though they might have learned that pressing the lever is associated with the tone, *the tone merely predicts but does not cause the shock*. If, on the other hand, the rat encodes the tone-shock relationship as causal, then the rat should avoid pressing the lever, which in the past had also led to the presentation of the tone because the tone itself is perceived as a cause of shock, which is to be avoided. This experiment provides perhaps the best direct evidence for causal induction of a cause-effect representation in a nonhuman animal.

#### Concept Learning

The ability to discriminate stimuli based on category membership exemplifies conceptual behavior. Concept learning involves the process of stimulus classification based on a generalizable rule or property. There are three types of concept that animals have been shown capable of learning: perceptual, functional/equivalence, and abstract/relational. Category membership in a perceptual concept is defined by perceptual features of the item, as illustrated by the classic experiments by Herrnstein et al. (1976). Pigeons were reinforced with food for responding to photographs that contained pictures of people or parts of a person (e.g., a face) but were not reinforced for responding to photographs that did not contain pictures of people. Pigeons were able to learn this person/no-person discrimination. Pigeons were not merely learning the correct responses to each picture of the training set. Instead, they showed true concept learning in that their discrimination performance transferred quite accurately to novel pictures that did or did not contain humans in them. Much evidence has accumulated as to the general ability of nonhumans to acquire perceptual concepts (Lea et al. 1993; Wasserman et al. 1988) and include not only discrimination of

objects but also of actions and movement (Cook et al. 2001; Dittrich et al. 1998).

A functional concept involves the classification of items based on their functional similarity, such as furniture, tools, etc. While the individual members of the category might be perceptually different from each other – such as a saw, sledgehammer, and miniature screw driver – they all share the same functional property, such as all being tools. Like a functional concept, an equivalence class is also defined by perceptually disparate items being grouped together based on sharing a common relation, such as an association with an outcome. By sharing a common associate, the items within the equivalence class become functionally equivalent. There is quite a bit of evidence that animals are capable of forming equivalence classes (see section [Stimulus Equivalence](#)). For example, after learning A–B and C–B associations (where A and C are sample stimuli presented on a center response key and B is a comparison stimulus presented on a side response key), pigeons that then learn a new A–D association will automatically have an increased probability of choosing D following C, despite never having been explicitly trained on a C–D relation (Urcuioli and Lionello-Denolf 2001). Equivalence category learning has received extensive attention in the animal learning and cognition literature (Bovet and Vauclair 1998; Hall 1996; Honey and Hall 1989; Zentall 1998).

Perhaps the most abstract form of concept learning involves categorizing stimuli based on their relational properties. Most of this work involves training subjects on a Same/Different discrimination, by which responding to a set of items is reinforced if the items are all the same as each other (“Same” category) or not (“Different” category). After successfully learning the discrimination, Same-Different concept learning is demonstrated by above chance transfer to novel items that also belong to Same and Different categories (Blaisdell and Cook 2005b; Wasserman et al. 1995; Wright et al. 1984). Chimpanzees (Gillan et al. 1981; Oden et al. 1988), and perhaps baboons (Fagot et al. 2001), macaques (Flemming et al. 2011), and pigeons (Cook and Wasserman 2007), may also have the capacity for

encoding higher-order relations (e.g., relational match to sample), such as those that underlie analogical mapping.

### Rule Learning

Another form of inductive learning involves the abstraction of a rule that defines the underlying structure or regularity among a set or sets of stimuli. Rule learning is typically studied by presenting the structured input to the subject and rewarding the subject for choice responses that conform to the rule. Evidence for rule learning must come from tests involving novel stimuli to see whether the subject has abstracted the rule. The subject should be able to apply the abstracted rule to novel stimuli. If not, then the subject may have simply memorized correct responses from the training set of stimuli.

One of the simplest rules, and with the longest history of study in animal cognition, involves the matching-to-sample (MTS) and non-matching-to-sample (NMTS) procedures. In these procedures, the subject is first presented with a sample stimulus (e.g., showing a red key light to a pigeon). Next two comparison stimuli are presented, one that matches and one that does not match the sample (e.g., a second red key light and a green key light). In a MTS procedure, the subject receives a reward (e.g., food) for choosing the comparison that matches the sample (red in this example); while in a NMTS procedure, the subject is rewarded for choosing the non-matching comparison (green in this example). While early work failed to find evidence for transfer to novel stimuli, therefore showing that such a procedure did not lead to true rule learning (Cumming and Berryman 1965), it has been subsequently shown that increases in the training set size led to increases in accuracy of transfer performance (Bodily et al. 2008), providing evidence for learning and applying an abstract rule of “choose same.”

More complex and sophisticated rule learning involves sequence information (Fountain 2008; Murphy et al. 2008), spatial patterns (Brown et al. 2000), number (Brannon and Terrace 2000; Scarf et al. 2011), syntax (Kako 1999), and artificial grammar (Herbranson and Shimp 2008;

van Heijningen et al. 2013). Dissociations between bottom-up associative accounts and top-down rule induction accounts of serial pattern learning have been reported in rats (Wallace and Fountain 2002) and pigeons (Garlick et al. 2017).

### Tool Use, Physical Cognition, and Theory of Mind

There are numerous reports of tool use in the animal kingdom. While many such instances likely involve noncognitive processes such as innate mechanisms (e.g., bird nests, spider webs, etc.), some examples have attracted the attention of more cognitive accounts. Some of the most likely candidates for rational processes in tool use involve apes and birds, and utilize physical traps (Mulcahy and Call 2006; Logan et al. 2014; Tebbich et al. 2007), string pulling (Taylor et al. 2010; Werdenich and Uber 2006), and even optimal tool construction or modification (Weir and Kacelnik 2006).

Some of the abilities that underlie rational tool use and construction involve more general processes that are collectively referred to as *physical cognition*. Physical cognition includes object permanence (Mendes and Huber 2004), causal effects of physical properties of objects (Call 2007; Helme et al. 2006), and means-ends relations (Krasheninnikova et al. 2013). A related domain of rational behavior involves predicting the behavior of, and communicating with, other agents. This domain is referred to as theory of mind and involves holding beliefs about one's own or other's beliefs and knowledge. Evidence for true theory of mind (i.e., mindreading) versus a theory of behavior (i.e., behavior reading) in nonhumans is contentious (Call and Tomasello 2008; Heyes 2015).

### Conclusions

I have reviewed evidence for rational processes in animals. Many animals show evidence for rational processes falling into two domains: deductive inference and inductive inference. These types of rational processes have been the direct focus of empirical study. Furthermore, there is a large and growing literature on physical cognition and theory of mind in animals, which touch on both domains of inference.

Given the extensive evidence for a variety of rational processes in animals, the question should be asked, are there any rational processes that seem beyond the capacities of nonhuman animals? Actually, there are. Abductive reasoning has yet to receive serious attention in the animal literature. An abductive inference involves the process of seeking and assessing explanations (Johnson et al. 2015; Turrisi 1997). Unlike deductive reasoning, in abductive reasoning the premises do not guarantee the conclusion. Instead, an abductive inference is derived from the strength of the premises and can be thought of as a likely (or best) explanation for the state of the world that brought about the conclusion. The few studies that have investigated whether nonhumans seek explanations have compared human children to chimpanzees. In contrast to human children, who have the natural proclivity to seek explanations for anomalous or unexpected events, chimpanzees fail to display this capacity (Povinelli and Dunphy-Jelii 2001).

Another rational process for which there is extensive evidence of absence in animals is true language. As opposed to many forms of communication found throughout the animal kingdom, true language is recursive and open-ended such that any meaning may (in theory) be communicated symbolically (e.g., through spoken or written word, signs, tokens, etc.). Even great apes, parrots, and dolphins that have received extensive symbolic training – such as with lexigrams, signs, or vocalizations – acquire only rudimentary properties of language, including syntax and vocabulary (Kako 1999; Pepperberg 2017). Some have taken this, and the poor quality of evidence for true theory of mind, to argue that there exists a deep divide between human and nonhuman minds (Penn and Povinelli 2007; Penn et al. 2008). This may be the case, but for now it is still an open, empirical issue that awaits further testing.

## Historical Background

Reaction Time (RT) data have been used as a measure of human behavior throughout the history of psychology. The Dutch physiologist Franciscus Donders (1969) believed that RTs were a window into *mental chronometry* or the duration of various mental operations that included perceiving a stimulus, recognizing it, and making a choice. His methodology heavily relied on a subtraction method in which tasks purportedly with and without various mental components were compared. The difference in reaction time between two tasks that varied in one task component was assumed to measure the duration of that component. For example, the two tasks could require deciding whether to push a button when a stimulus appeared versus pressing any button when it appeared. Trials involving a button press for the former task might produce RTs that average 65 ms longer. Using Donders' logic, this suggests that the mental process of deciding is 65 ms in duration. The basic assumptions of the subtraction method were questioned (Kulpe 1909) largely because the addition of a new task requirement could fundamentally alter the way in which ongoing task components were processed by the brain. In the button press example, it is possible that requiring the participant to decide whether to press the button may also alter the way that the stimulus properties are perceived or the attention directed to the task.

In studies of human cognition and perception, reaction time is a critical variable in the study of choice. A choice that is made more quickly is assumed to be easier. When discriminating between two very similar stimuli, RTs will be longer than when the two stimuli are very different. If there is a “correct” choice, the error rate will

also be higher for harder discriminations. Although this relationship between reaction time and difficulty can be weakened by either encouraging fast RTs on every trial or giving people an unlimited amount of time to make a choice (thus producing the speed-accuracy trade-off, Henmon 1911), long RTs and high error rates are usually coupled for tasks in which at least one choice is designated as correct.

The utility of RTs for human experiments is rooted in their continuous nature that allows the experimenter to know whether a particular choice was easier or harder than other choices even when the categorical response (chose the “left” button or the “correct” button) was identical. For example, a person categorizing stimuli as “red” or “violet” may have chosen the same response for a deep red stimulus and a reddish-purple stimulus, but the reaction time for the first choice is likely to be much shorter than that for the second. In sum, reaction time has proven a useful metric of choice difficulty in human experiments.

In comparative psychology, however, reaction time has played a much smaller role than it has in human experiments. The key variable for most experiments involving the nonhuman animal is the choice – did the animal choose the left lever or the right? One of the reasons that reaction time is rarely utilized in studies of nonhuman species is that there are so many uninteresting factors that influence the speed at which an animal will choose. Unlike humans in a laboratory that sit in front of a display with their fingers poised on the response keys, rats, pigeons, and mice in an experimental chamber can spend an inordinate amount of time grooming themselves, not looking at the stimulus, and performing other nontask behaviors. This additional variability makes reaction time data especially noisy in animal studies.

For example, Fig. 1 shows a frequency histogram of a subset of 57,098 RTs for a study of object recognition by pigeons. The raw RTs are extremely skewed and highly variable, varying from 0.02 s to 186 s (i.e., over 3 min; the 42 responses longer than 15 s were omitted from Fig. 1). Using the most powerful tools currently at our disposal (multilevel modeling after RT transformation) without aggregating the data, the only

effect of any importance was all too obvious – when the stimuli were randomly assigned to choice keys rather than assigning all objects of the same class to the same response key, the pigeons took longer to respond (2.2 s vs. 1.1 s). So, despite the extremely large sample size, it was difficult to assess reaction time differences for any but the largest and most obvious effect.

To appreciate the problem with reaction time in the typical animal experiment, consider a study in which a pigeon performs a series of trials in which a stimulus is centrally displayed and two response keys are presented. In the typical design, the pigeon is required to peck at the stimulus one or more times (the orienting response) thus acknowledging that the pigeon has seen the stimulus. After fulfilling this peck requirement, the response keys are then made available. Given the amount of time required to peck the stimulus, the neural processes supporting a decision may have occurred long before the response keys were even displayed. Indeed, the location of the last orienting response will affect the speed at which an animal can move to each of the response keys.

Another complicating factor in animal studies is that animals differ in key preference (e.g., showing a side bias). In human studies, this is readily addressed by either switching the stimulus-response assignment during the experiment (within-subject counterbalancing) or having each subject assigned to a different stimulus-response mapping (between-subject counterbalancing). This type of counterbalancing is less common in animal work because the slow learning of a new mapping can complicate within-subject counterbalancing, and the small sample size of the typical animal study may be insufficient to be confident that between-subject counterbalancing will increase the validity of RTs.

There are some preparations using nonhuman animals that have produced much cleaner reaction time data. Some primate studies use designs in which the subject holds a joystick that is moved from side to side, thus eliminating many of the inattentive nontask behaviors that might be produced between stimulus onset and the response (Heimbauer et al. 2012; Hopkins et al. 1989). Another design successfully used with primates

simply registers the onset of an eye movement to a location (Roitman and Shadlen 2002). For rats, designs that require the subject to be located at the lever can produce more useful reaction time data. This requirement has been implemented by requiring a rat to hold down the lever and to only release it when a response is necessary (Baunez et al. 1995; Laubach et al. 2000). Although the resulting RTs are much less variable, this design is not easily translated into studies requiring a subject to choose between multiple options.

Donald Blough and colleagues have had some success in eliciting reliable RTs from pigeons. Blough and Blough (1978) projected small stimuli on a response key approximately once every 20 s and measured the elapsed time between the presentation of the stimulus and a pigeon's peck. Like the design involving a rat holding down the response key, the strength of this design relies on the subject being poised over the response key thus eliminating the variability created due to nontask behaviors. A different design used in Blough (2002) served a similar purpose and likewise produced useful RT data. In this task, a cue occurred immediately before the target stimuli, but in the same location as the stimulus that was contingently reinforced. The cue was a valid cue for some target stimuli but not for others, so it was possible to use the RT duration as an assessment of the pigeon's expectation regarding what would follow.

For rats and pigeons, each of the designs that generated valid and reliable RT data are, in essence, go/no-go designs in which the subject either responded to a stimulus (released the lever or pecked the key) or did not. There is one reported use of RTs for a choice task in the pigeon that overcame the problems typically present in nonhuman studies of choice. Blough (2009) required pigeons to discriminate between 5 mm spots of light separated by 6 cm, and the selection of one or the other stimulus was registered if a peck occurred within 0.5 cm to the left or right of it. Given the small size of the stimuli, it was possible to place them in close enough proximity to the ready cue that nontask behaviors between stimulus presentation and the response were

greatly reduced. Of course, this type of design places significant constraints on the size (and thus complexity) of the stimuli to be discriminated. Consequently, producing useful RT data for choice tasks is likely to continue to prove problematic for many species.

### Other Time-Based Measures Used in Studying Animal Cognition

Two measures related to reaction time that have been regularly used in comparative psychology are the time to complete a task (e.g., latency to finish a maze, or when finding a stimulus among many which is not the latency of a reaction but rather the duration of a search) and the rate of responding (e.g., how quickly a pigeon is pecking at a stimulus, often assessed by interresponse time but also indirectly assessed by the number of responses that occurred during a constant time interval). Although these are not RTs, the analysis of these time-based measures present many of the same analysis challenges raised in the next section due to the skewed nature of temporal variables. Subjects have a floor on how quickly they can respond but often no ceiling on how slowly, and this asymmetry can create a skew in the dependent variable that should be considered in statistical analyses (see Fig. 1).

**Reaction Time, Fig. 1** Skewed distribution of RTs

## Current Uses and Theory

Because of the issues raised earlier, RTs are not common in contemporary studies of nonanimal behavior. As a result, many researchers who do examine reaction time and other latency measures are not familiar with the challenges that these data present. Thus, this treatment will draw heavily from what has been learned in human reaction time studies to help the comparative psychologist confront these challenges.

First and foremost, RTs and other latency measures are heavily skewed. A subject can only respond just so fast to a stimulus (limited by the speed of neural processing) thus placing a floor on RTs, but very long RTs are not unusual, especially when nontask behaviors occur. There are multiple approaches that can be and have been used to deal with this skew, although some researchers rely on the ill-informed assumption that their favorite analysis technique is robust to violations of normality (Bradley 1978; Harwell et al. 1992). Interestingly, the principal problem is not non-normality per se but rather the heterogeneity of variance that inevitably occurs in the presence of nonnormal distributions of residuals. Current approaches include: (a) analyzing the median reaction time, (b) truncating the upper tail of the distribution, (c) transforming the RTs, (d) use of generalized linear modeling to fit an alternative distribution, and (e) fitting mixtures of multiple distributions. The following paragraphs will describe each of these in turn along with recommendations regarding their use.

### Analyzing Median RTs

The mean is not the appropriate measure of central tendency for reaction time data because it is affected by extreme observations and possible outliers in the right tail. The median is commonly used as an alternative measure of center for skewed data (Miller 1988) because it is more robust to extreme outliers than the mean. However, several issues arise when analyzing median RTs. This estimator varies more than other sample statistics leading to a significant decrease in power (Ratcliff 1993). Still, if it can be assumed that the probability of outliers is not consistent across

conditions, the median may be the most stable estimator. Another concern with using median RTs in analyses is their effect on linearity. Linear trends in the mean are not necessarily linear trends in the median (Ratcliff 1993). Generally, unless the specific location of the true center of the distribution is of interest, the median is not a particularly good sample statistic. Finally, any form of aggregation before analysis loses information about the uncertainty in that summary statistic as well as the sample size on which it was based.

### Truncating the Upper Tail

An outlier is an observation produced by a mental process other than the one of interest (e.g., experimenter error, loss of attention, fatigue, etc.). These observations interfere with the analysis and obscure the effects of legitimate responses and thus should be eliminated. However, valid yet extreme values should be retained and properly accounted for in the analysis. The distinction between extraneous and valid RTs is important for drawing accurate conclusions, but the proper classification is challenging because they coexist in the tails of the distribution. In reaction time data, most outliers will occur in the upper tail of the distribution, hidden among the other very long but valid RTs (Baayen and Milin 2010; Ratcliff 1993).

This long right tail is problematic for a conventional analysis, and researchers often resort to truncating, or omitting, these “outliers” in order to increase statistical power. The problem with truncating very long RTs is that researchers are often truncating valid responses. Common truncation methods involve using an a priori range of acceptable RTs (Ulrich and Miller 1994). The most common technique is eliminating data that are two to three standard deviations beyond the mean. However, because the mean is not a good measure of central tendency for skewed data, it is also not a good measure for identifying outlying responses. Because of the skew in reaction time data, this method of truncation will cause more observations in the upper tail to become eliminated than from the lower tail. This creates a downward bias when estimating parameters and fitting models to the data (Ulrich and Miller

1994). Because of the difficulty in distinguishing outliers from valid responses, truncating observations in the tails may lead to failing to exclude some illegitimate and very influential data values or to excluding legitimate responses (Baayen and Milin 2010; Ratcliff 1993). Although including outliers does add unwanted variability to the data, the bias caused by significant truncation is much more harmful and should be avoided (Ulrich and Miller 1994).

In spite of the danger in truncating valid responses, truncating obvious errors is necessary for obtaining accurate results. Some RTs may simply be impossible. For example, negative or extremely small RTs are not physically possible. Any reaction time less than 150 ms is measuring an anticipatory response and not an actual reaction time. Likewise, a decision reaction time involving minutes (which is quite possible in animal experiments) is arguably the result of inattention, grooming, and other nondecision behaviors.

### Transforming RTs

Transforming the original data can help minimize the effects of outliers and reduce heteroscedasticity (Bartlett 1947; Van Breukelen 2005). Transformation creates a dependent variable that can be analyzed using familiar linear methods of statistical analysis (e.g., regression and ANOVA). Commonly used reaction time transformations are logarithmic, inverse, and square root transforms (Bartlett 1947).

There are three known issues with transformations, (a) some transformations may not reestablish normality (Baayen and Milin 2010), (b) transformations can make it difficult to interpret the results within the transformed space, and (c) they can create complications when trying to convert back to the original scale (Bartlett 1947; Erceg-Hurn and Miroseovich 2008). To be maximally useful, researchers should consistently use the same transformation so that the results of one study can be readily compared to those of other studies. It is possible, however, that similar designs may produce RT distributions that are differentially affected by the same transformation. The transformation could actually introduce skew where none exists or undercorrect the existing

skew. Furthermore, applying nonlinear transformations (i.e., log, inverse, etc.) changes the original ratio scale. For example, a multiplicative effect in the raw data becomes an additive effect once a logarithmic transformation is used. This issue becomes problematic when trying to back-transform the results into the original units and when trying to assess interactive effects. When RTs are transformed, the direct connection with the mental processes can be lost (Lo and Andrews 2015). Lo and Andrews (2015) demonstrated an additive to overadditive effect in raw lexical data, but an underadditive effect when an inverse transformation was applied. This difference is notable because an additive to overadditive model suggests independent, serial processing between predictor variables whereas an under-additive model suggests interactions between predictors.

An additional issue when transforming RT data is ensuring that basic summary statistics like the mean are properly reported. Generally, researchers are only familiar with the arithmetic mean which is computed by adding the values and dividing by the sample size. However, a geometric or harmonic mean is a better measure of central tendency for heavily right skewed data (Sauro and Lewis 2010; Wainer 1977). The harmonic mean is based on the speed of a response and is less affected by the long right tail, but the geometric mean is based on log-transformed values and generally fits RT data better (Sauro and Lewis 2010). The harmonic mean is also more sensitive to outliers.

While transforming data to permit the application of general linear models is simpler than determining the underlying distribution and applying a generalized model (discussed below) and is certainly superior to aggregating the data before analysis, transformation should be done with awareness of the consequences for interpretation.

### Generalized Linear Modeling

A more complex but more accurate approach is to apply generalized linear models to RT data. Research on the benefits of generalized linear modeling is limited but suggests a greater ability to model the more nuanced nature of RT data. The generalized linear modeling approach

encompasses general linear models, such as linear regression and ANOVA, as a special case in which the assumed distribution of the residuals is normal. The advantage of generalized linear modeling is that it allows the analyst to specify alternative assumptions about the distributions of the data.

Historically, these models have not been attractive for researchers due to their complexity, limited development (e.g., a lack of repeated measures versions), and necessary computational power. Applying a generalized linear model required mastery of the specific model to be used and extensive mathematics that was beyond the area of expertise of nonmathematical researchers. In addition, each nonnormally distributed dataset required a unique, nonlinear model. Accordingly, linear modeling became the gold standard in most research.

However, with the advent of statistical modeling computer packages, generalized linear modeling has become more accessible. Currently, major statistical packages include options that allow researchers to select from numerous distributions with just as much ease as selecting a linear model. Given that RT data has skew that may be best modeled using alternative distributions like the Gamma or Weibull (Van Zandt 2000), future analysis of RTs may be best accomplished by using a model that uses a more appropriate distribution than the normal without requiring a transformation to normality. At this point in history, only a few researchers are adopting this approach, but it is expected to grow as researchers obtain training in generalized linear modeling.

### Mixtures of Distributions

Some data analysts have posited that RTs may be arising from multiple independent sources thus producing multiple superimposed distributions (e.g., Dolan et al. 2002). This approach is rarely utilized due to limitations in software for fitting mixture models, but it rests on the assumption that there are multiple sources driving recorded RTs. Reaction time distributions are considered the result of the superimposition of multiple distributions, one for each task component. For example, the ex-Gaussian approach combines an

exponential distribution with a Gaussian (or normal) distribution (Dawson 1988; Ratcliff and Murdock 1976). The exponential is assumed to arise from decision processes that are superimposed on a Gaussian reaction time distribution.

More generally, reaction time distributions could arise from combining multiple processes like reactions to the stimulus and nontask behaviors (Blough 2011; Ratcliff et al. 1999). Thus, a distribution could have two or more modes depending on which behaviors are evidenced on a particular trial. Mixture-based approaches attempt to estimate the parameters of each distribution along with the likelihood that a particular measure was drawn from one distribution rather than another.

### Other Issues Arising in the Analysis of RTs

*Practice Effects.* A ubiquitous source of variance in RTs is due to practice effects. Not surprisingly, the more practiced a subject, the faster the RTs. In human studies, the effects of practice are often the strongest source of RT variability in a study. Thus, isolating this source by including trial (or its logarithmic transformation) as a predictor in a statistical model can significantly increase the power of a data analysis. It can also be important to include predictors like trial or session in interactions with each independent variable in order to assess whether the effect of that IV is increasing or decreasing over time. For example, a subject's RTs may be insensitive to a variable like stimulus size early in training but show increased sensitivity with practice. Some comparative psychologists, however, train an animal to asymptote before introducing an intervention thus precluding the study of RT changes across time. Furthermore, temporal predictors are often blocked so that the data can be subjected to an analysis of variance (ANOVA) rather than identifying the functional relationship between a time-based level like trial and reaction time (Young 2016).

*Censored Data.* A common problem with animal studies involving any type of latency to a response is the possibility that the subject will simply not respond in a timely manner. Some designs may have a response deadline before a trial terminates and the next trial begins. This

raises the question of how to treat these missing RTs. Two approaches are common although a third is optimal.

First, the value could be replaced with the maximum possible that could be observed (i.e., equal to the deadline latency). For example, if a rat is given 90 s to find a hidden platform in a water maze, then a failure to find the platform is treated as a latency of 90 s. In his treatment of search times, Blough (2002) treated trials on which a pigeon had not responded by the end of the 10 s display of a search display as having a 10 s RT. This approach can be problematic because it can distort the RT distribution and create bimodal residuals when there is significant censoring. It also assumes that all failures to respond should be treated equally as being at the minimum possible RT for response failures, thus decreasing the RT variance.

Second, the trial may be treated as having a missing value. This approach acknowledges that the actual RT is unknown. However, these missing values are not missing at random which is a prerequisite for the optimal statistical treatment of missing data. It is not that the subject has an unknown RT (any value between zero and infinity) but rather that the RT is greater than a particular threshold (it can be any value between the deadline and infinity).

Third, the values are replaced with the maximum possible as in the first method, but these data are subjected to a censored regression that explicitly attempts to fit a distribution that acknowledges that this maximum value represents a value beyond the censoring threshold, but the value is treated as being in an unknown range.

To compare and contrast these approaches, Fig. 2 shows three illustrations of the consequences of different treatments of an RT distribution. The distribution on the upper left assumes that every trial generated a known RT. For the middle distribution, there was a deadline to respond, and any trial without a response occurring by that deadline was treated as having a value at the deadline. For the distribution on the upper right, RTs greater than the deadline are simply treated as missing. Both of the approaches illustrated on the upper right and bottom produce a

mean RT and standard deviation RT that were lower than the complete (ideal) distribution on the upper left (5% and 5% lower for the replacement method, 25% and 14% for the missing value method; of course, these values would be different for different distributions but should always be smaller). Thus, both approaches distort common statistical summaries of the data.

Censored regression is the proper analysis technique for fitting censored data and would be conducted on the data in the upper right panel. Unfortunately, scientists are often unfamiliar with the consequences of censoring, and repeated measures versions of censored regression are not broadly accessible. The effects of response deadlines on an analysis will depend on the response threshold and the amount of data that is censored. A response deadline may result in a large degree of censoring early in an experiment but, as subjects adapt to the deadline, the censoring may be rare later in an experiment. Regardless, it is recommended that researchers avoid the use of response deadlines that will result in a level of censoring that is obvious to the eye.

*The Speed/Accuracy Tradeoff and the Analysis of Errors.* A common observation in experiments in which one response is correct whereas others are incorrect is that subjects will show a speed/accuracy tradeoff: the faster that a subject responds, the greater the likelihood of making an error. This self-evident fact has consequences for the treatment and interpretation of RT data. To handle the potentially different meanings of correct RTs and incorrect RTs, researchers have either only analyzed correct RTs, used accuracy as an additional predictor in the analysis, or treated all of these RTs similarly.

The first approach sidesteps the speed/accuracy tradeoff by ensuring that all of the analyzed RTs are from correct trials. This approach is usually taken when errors are generally rare because otherwise it can result in a significant loss of data for analysis. The approach also makes the untenable assumption that all correct trials are equal, whereas some correct responses may be the result of guessing and only inadvertently correct.

The second approach has the advantage of not losing any data, and it isolates a potentially large

**Reaction Time, Fig. 2** RT distributions when not truncating at a deadline (left), truncating at a deadline (middle), and omitting data beyond the deadline (right)

source of variance in RTs (correct vs. incorrect). It has two drawbacks, however. First, if the independent variables covary with accuracy, as they often do, then adding accuracy as a predictor will result in accuracy competing to account for the same variance as the independent variables. Second, if some conditions produce few or no errors, then many analysis techniques will fail due to the design imbalance created.

The third approach must be coupled with a separate analysis of accuracy. For example, an analysis may show that the independent variables have no effect on accuracy but a significant effect

on RTs or vice versa. It is also common to observe that one or more variables increase accuracy while also decreasing reaction time, an indication that performance is improving in multiple ways.

*RT Validity with More than two Response Options.* Even in humans, the validity of RTs decreases as the number of response options increases because choosing among more than two responses is less automatized and may require searching for the right option among many. This search process thus contaminates RTs with additional nontask behaviors. For humans, the use of voice as a response can overcome this problem,

but so can other highly automatized multiple-response behaviors like typing on a standard keyboard for a skilled typist or using a gaming console for expert video game players. For nonhuman animals, this same benefit might be achieved by using eye tracking or direct assessment of neural behavior that precedes a response. In general, however, most researchers would be well-served with an initial focus on two-alternative choice tasks when RTs are to be collected and analyzed.

Unresolved Issues

Are Different Distributions Expected to Occur for Specific Paradigms or Species?

In human experiments involving RTs, nontask influences on RTs are typically much rarer than those occurring in nonhuman animals. Different paradigms have been shown to be more or less likely to produce nontask behaviors that influence the measured RTs, and different individual members of a species may be more or less likely to do so. Figure 3 shows plots for eight pigeons in an object recognition choice task. It is evident that some pigeons predominately made their choices soon after the choice keys were displayed (e.g., the four on the right of Fig. 3) whereas others

(notably, 11Y) showed more variable and delayed choices. Are some subjects producing few if any nontask behaviors whereas others are much more likely to spend time grooming, exploring, or resting? If so, distributions for the latter subjects may not only be more variable but may actually include multiple RT modes that complicate interpretation.

A related issue arises when comparing RTs across species or behaviors. Given that a response to a visually presented stimulus requires orientation toward the stimulus, species for which hearing is dominant might show different RT profiles if the stimuli were auditory because auditory stimuli do not require orientation to a specific location to identify the stimulus before responding. Finally, species or behaviors that tend to have long RTs or latencies are less likely to be skewed and may produce normal RT distributions.

Can Neural RTs Realize Donders’s Goals?

Donders (1969) originally set out to measure the duration of neural processes. Given that technological advances are providing the opportunity to measure the brain’s response to stimuli and the time at which a neural region changes activity, assessing the reaction time of multiple neural

Reaction Time, Fig. 3 RT distributions for eight pigeons

regions may provide the tool to address concerns like Kulpe's (1909). However, the original concerns about the subtraction method have arisen in brain imaging when making comparisons across tasks (Friston et al. 1996). Although the goal of mental chronometry is laudable, realizing this goal will not be easy.

## Reafference Principle, The

Jessica X. Brooks<sup>1</sup> and Kathleen E. Cullen<sup>1,2</sup>

<sup>1</sup>Department of Physiology, McGill University, Montreal, QC, Canada

<sup>2</sup>Biomedical Engineering, The Johns Hopkins University, Baltimore, Maryland, USA

### Definition

The principle of reafference is a theory proposed by von Holst and Mittelstaedt in 1950. This theory proposes that the brain distinguishes reafferent (self-generated) sensory stimuli from exafferent (externally generated) sensory stimuli based on an internal copy of an outflowing (efferent), movement-producing signal generated by the motor system.

### Introduction

Our sensory systems gather information in order to build an accurate estimate of the outside world. In turn, this information is used to guide our behavior. In everyday life our sensory systems are stimulated not only as a result of events in the external world (termed sensory “exafference”) but also as a result of our own voluntary actions (termed sensory “reafference”). In order to

achieve accurate perception and motor control, it is critical for the brain to distinguish between these two broad categories of sensory stimulation.

**Functional significance:** This ability to distinguish between sensory exafference and reafference is vital at multiple levels of sensory processing. For example, at the most basic level, it is essential in the context of reflex generation that the sensory stimulus is correctly assigned as originating from an actively generated movement rather than an externally applied stimulus. Consider the example of slipping on ice. In this situation, the corrective movements generated by vestibulospinal reflexes are essential for maintaining balance. In contrast, if a similar movement was actively generated as a voluntary movement, vestibulospinal reflexes would be counterproductive since they would counteract the intended movement. Likewise, the ability to distinguish between sensory exafference and reafference is a hallmark of higher-level cognitive functions; it is essential to know whether the origin of sensory stimulation is externally or self-generated. Indeed, a misinterpretation of “self-generated” versus “external world” has been implicated in psychiatric disorders such as schizophrenia.

**Original formulation:** Our ability to distinguish between sensory exafference and reafference has long been appreciated. Notably, in the nineteenth century, Helmholtz observed that we do not sense the visual world moving across our retina when we make voluntary fast eye movements. Yet tapping on the canthus of our eye – an external event that causes the eye to move at comparable velocity – creates the illusion that the world is moving (Helmholtz 1925). To help explain this, Sperry coined the term corollary discharge, to refer to information originating from a motor area sent to a sensory area in order to modulate the response of this sensory area to sensory inputs that are the result of voluntary actions (Sperry 1950). In the same year, von Holst and Mittelstaedt proposed a more specific formulation of this idea termed the principle of reafference. This principle states that, during active movements, a copy of the motor command is sent to sensory areas to cancel sensory

information that is the result of active behavior (von Holst and Mittelstaedt 1950). In turn this framework has subsequently been used to explain the result of perceptual studies. For example, the principle of reafference has been used to explain why we cannot tickle ourselves. Specifically, it has been proposed that a copy of the motor command that generated your voluntary movement is used to suppress the tactile sensory information (Blakemore et al. 1998).

*Evidence from sensory systems in model organisms:* Since the 1950s, electrophysiological studies in model systems have provided evidence for principle of reafference. These include experiments in the auditory system of the cricket and mechanosensory system of the crayfish. In each of these systems, the reafferent sensory stimulation is removed from further processing in order to correctly interpret and emphasize external stimuli (reviewed in Cullen (2004) and Crapse and Sommer (2008)), providing support for the reafference principle. Insight into the reafference principle has also been provided from experiments in the weakly electric mormyrid fish, where movement of the fish's body during its electric organ discharges alters incoming sensory input (reafference). A series of elegant studies revealed that efference copy signals are sent directly to the second-order principle cells to cancel reafferent sensory information regardless of whether the actively generated electric discharge is actually allowed to occur. Specifically, when the animal is prevented from generating an electric discharge, the investigators observed a "negative image" (or cancellation signal) in second-order principal cells that would have cancelled the self-generated sensory information if it had been allowed to occur (Requarth and Sawtell 2011).

*More sophisticated computations occur in mammalian systems:* More recently electrophysiological studies have tested the principle of reafference in mammals for the processing of vestibular information during self-generated motion. Reafferent vestibular information is indeed substantially suppressed in rodents and primates at the first central stage of processing in the vestibular nuclei (reviewed in Cullen 2012), as well as at the next stages of sensory processing in the vestibular cerebellum (Brooks and Cullen

2013) and vestibular thalamus (Dale and Cullen 2017). However, the mechanism operating in the vestibular system appears to differ in a significant way from the classically stated formulation of the reafference principle. Specifically, in contrast, to what is observed in the electric fish, the mechanism underlying the suppression of vestibular reafference is more sophisticated. Neurons in the vestibular nuclei, deep cerebellar nuclei, and thalamus do not receive direct efference copy information, such that a negative image is never observed when head movements are prevented. Instead, a cancellation signal is only present in behavioral conditions where the actual sensory feedback matches the brain's estimate of the sensory consequence of a voluntary movement. This more sophisticated mechanism allows the brain to emphasize unexpected sensory inputs that occur either because of inaccurate motor control (expected sensory feedback doesn't match actual sensory feedback) or because of unexpected externally imposed motion (exafference).

## Conclusions

Despite long-standing interest in the computations required for accurate motor control, the neural mechanism underlying the computation of sensory exafference in mammals remains unknown. In particular, to date, where and how the cancellation signal is generated is still an open question. There are many reasons to believe that the cerebellum plays a critical role in the implementation of the reafference principle. Studies in the electrosensory system of fish have shown that their cerebellum-like circuitry computes predictions about the sensory consequences of the animals' own behavior, brain imaging studies in humans show increases in cerebellar activity when sensory tactile feedback does not match what is expected (Jenmalm et al. 2006), and finally, neurons in the primate cerebellum, more specifically the rostral fastigial nucleus, one of the deep cerebellar nuclei, have been shown to encode unexpected vestibular signals (i.e., vestibular exafference; Brooks and Cullen 2013). Although these results support the idea that the cerebellum is part of the circuitry underlying the implementation of the principle of reafference,

ultimately, further studies in the cerebellar cortex and deep nuclei are required to provide a better understanding of the mechanism and neural circuitry underlying the suppression of sensory reafference.

## Definition

Representing mutually exclusive alternatives (“A or B”), ruling out one or multiple alternatives (“not A”), and thereby concluding that the remaining alternative must be true (“therefore B”).

## Introduction

Reasoning has long been regarded as an exceptional ability that makes humans unique, but this notion has been heavily challenged in the past century. A growing body of evidence suggests that many animals are capable of reasoning, even at levels comparable to young children. However, reasoning is a broad concept that encompasses various abilities. One of the most widely studied reasoning abilities in animals is reasoning by exclusion, which is often defined

using the logical definition of disjunctive syllogism: “A or B, not A, therefore B” – in other words, reasoning that given options A and B and the knowledge that option A is incorrect, option B must then be correct. Although “reasoning by exclusion” and “process of elimination” are often used interchangeably with “disjunctive syllogism,” some researchers argue that these terms lack the deductive certainty of the disjunctive syllogism, meaning that we cannot know whether option B was represented as the *necessary* conclusion (Mody and Carey 2016; Pepperberg et al. 2019). Such conceptual and methodological issues are highlighted in this review of reasoning by exclusion in animals, which has become an area of growing interest in the last two decades.

The ability to reason by exclusion may provide animals with many benefits. A capuchin monkey may knock on a branch to listen whether something edible is hidden inside. The ability to exclude locations based on this feedback can save him both time and trouble attempting to extract a non-existing treat. A hungry house cat chasing a mouse may find one possible hiding spot empty and then reason that her prey must be hiding in the other location. Various selective pressures may have given rise to this ability (De Petrillo and Rosati 2020; Petit et al. 2015). However, such behavior can arise through numerous cognitive processes, with reasoning by exclusion being only one explanation. Is the capuchin monkey actually considering the contents of the branch, or has he learned to avoid certain cues after previous failures? Did the cat perhaps smell the mouse near the second location? Excluding such alternative explanations is an important reason for investigating reasoning by exclusion in controlled experiments.

The earliest study on reasoning by exclusion dates back to that of Grether and Maslow (1937), in which several monkey species were presented with two cups, of which one held a reward. The monkeys were allowed to choose after observing that one cup was empty. They chose the correct cup more often than expected by chance. This experiment presented the basic idea on which almost all future methodologies would be based, but the topic received little attention until the

influential studies by Premack and Premack (1994) and Call (2004). While Call’s study built further on the methodology of Grether and Maslow (1937), Premack and Premack (1994) took a slightly different approach. Their chimpanzees witnessed an experimenter hiding two different but equally desirable treats (A and B) under two cups. The cups and experimenter were then briefly blocked from sight of the subjects, after which the experimenter could be seen eating one of the two food items. The rationale behind this method was that the chimpanzees would first need to infer that the cup where treat A was hidden should be empty if the experimenter was eating A. By excluding that cup, the chimpanzees can conclude that the remaining cup must be the only rewarded option left, containing food item B. While such a task may seem easy to us, only one of the four chimpanzees succeeded consistently.

The methodologies used to test for reasoning by exclusion are subject of heavy debate. Successful performance in these experiments is often attributed to mechanisms other than reasoning by exclusion, such as learned solutions, behavioral biases, or avoidance of empty locations. Unsuccessful performance is often ascribed to the detrimental effect of interfering factors – such as poor attention, motivation, memory, or inhibition – which may mask the extent of reasoning abilities. Various methods have been developed to offer more conclusive tests of reasoning by exclusion in animals.

## Two Cups Task

The two cups task was the first method used to test for reasoning by exclusion (Grether and Maslow 1937) and is the most common method to date. The diverse methods all involve two cups (or similar opaque containers) and incomplete information on the location of one or multiple food items, followed by the opportunity to choose one of the cups. The tasks can generally be considered as either more similar to that of Call (2004), with only one cup being baited and the empty one shown to the subject, or more like that

of Premack and Premack (1994), with each cup having a different reward type and one type shown to the subject (Fig. 1).

**Reward Location**

Call’s version is the most common version of the two cups task. The original study involved great apes that observed two cups hidden from view

behind a screen. A reward, usually in the form of a favorite treat, is shown to the subject and then placed under one of the cups. The screen is removed, and the experimenter provides information on the content of one or both of the cups to the subject, which is then allowed to make a choice (Fig. 1). This information is given acoustically by shaking the cup or visibly by lifting the cup and

**Reasoning by Exclusion, Fig. 1** Schematic overview of the two cups task in the most common visual variations: reward location (left) and reward identity (right). Rewards are represented by stars, and arrows indicate whether a

reward is placed (pointing downward) or removed (pointing upward). Correct and incorrect choices are shown by check marks and crosses, respectively

revealing its content. The information given depends on the trial type and is generally one of four: information on both cups, baited cup only, empty cup only, or no information at all. The reasoning behind giving full information and only information on the baited cup is to ensure subjects can use visual or auditory information to locate the reward in this task. Trials where subjects receive information on only the empty cup are the ones that test for reasoning by exclusion. Trials with no information are carried out as a control, to ensure subjects are not using alternative solutions such as olfaction or experimenter cues.

Most great apes and monkeys tested on the visual version performed above chance level, but the prosimians tested thus far did not (Call 2004; De Petrillo and Rosati 2020; Hill et al. 2011; Petit et al. 2015; Völter and Call 2017). Other species that passed this task include dogs, dwarf goats, ravens, Clark's nutcrackers, and African gray parrots, whereas performance at chance level was found in sheep, pigs, Eurasian jays, jackdaws, and kea (Nawroth et al. 2014; Pepperberg et al. 2013; Plotnik et al. 2014; Schloegl et al. 2009; Tornick and Gibson 2013; Völter and Call 2017). Thus, there is a mixed phylogenetic distribution of this ability, even though apes, corvids, and parrots often reach similar performance on the same tasks (Lambert et al. 2019; Völter and Call 2017), which to a large degree may be due to differences in testing procedures (see below).

A strength of the two cups task is the possibility to adapt the testing modality to best suit a species. Most paradigms in animal cognition are vision based, but many animals are more reliant on other senses. Compared to the visual version, fewer species have been tested on the auditory task, and performance is generally poorer. The great apes in Call's (2004) study nearly always selected the correct cup when seeing the location of the food but less so when hearing a rattling noise of a shaken cup with food within. Those that passed the full information condition were then tested on the exclusion condition in which only the empty cup was shaken or shown. These individuals performed near ceiling level in the visual version but performed significantly poorer

yet still above chance in the auditory version. Controls of the auditory version involve noiseless rotations, tapping the baited cup, and a tape recorder playing sounds of a shaken cup. The apes failed to choose correctly in these controls, which suggests they relied on the causal connection between the presence of food and non-arbitrary sounds in the auditory exclusion task (Call 2004). However, other explanations for these results have been proposed, such as the recording not being a perfect replication of the actual sound and that subject may have associatively learned to use the combination of shaking and sound (Hill et al. 2011).

Most animals tested on similar conditions perform poorer on the auditory than visual version (De Petrillo and Rosati 2020; Hill et al. 2011; Plotnik et al. 2014; Völter and Call 2017). The importance of audition under natural circumstances does not easily translate into outstanding performance in the auditory task because the presence or absence of food has to be inferred through its interaction with the cup. In other words, the food itself does not produce sound, whereas it can directly be seen in the visual version. Interestingly, Asian elephants were unable to locate food by following an auditory cue, even though sound is an important modality for them. They could locate food by using olfactory cues and performed well on the olfactory version of the two cups task; they chose a baited container when smelling an empty one (Plotnik et al. 2014). In contrast to the auditory version, the olfactory and visual versions are more naturalistic and less arbitrary because the presence of the food item can be perceived directly, which likely aids reasoning based on the absence of such cues.

Most versions of the cups task require an experimenter to reveal the content of one of the cups. Touching and moving one of the cups, and not the other, is picked up as a social cue by some animals. They may subsequently choose the cup handled by the experimenter due to stimulus or local enhancement, which would result in poor performance when an empty cup is revealed or shaken. An efficient solution is to use inner cups that are placed over the reward but are never handled by the experimenter (Nawroth et al.

2014). The opaque outer cups are lifted simultaneously to reveal the inner cups, which are transparent or opaque depending on the experimental condition: two transparent cups for full information, two opaque cups for no information, and one of each for partial information.

Failure to succeed in these tasks can often be attributed to factors other than inability to reason by exclusion. False-negative results occur as animals may follow inadvertent social cues, become distracted, or rely more strongly on a modality not central to the test. On the other hand, success in these tasks cannot unequivocally show the use of reasoning. Animals may quickly pick up on the association between a cup being lifted or shaken and it never being rewarded, thereby learning to always choose the other option. Researchers should check whether there is an improvement in performance over trials, which is suggestive of learning. It has often been pointed out that the two cups task does not convincingly rule out a strategy based on avoidance of the empty cup. Before the content of any cup is known, an animal may represent both options as “maybe A, maybe B.” After learning that one cup is empty (“not A”), an animal can still be successful by looking in the only other location while still representing it as a possibility (“maybe B”). True disjunctive syllogism required deductive certainty (“therefore B”). Other methods are typically regarded as more conclusive (Mody and Carey 2016; Pepperberg et al. 2019).

### Reward Identity

In Premack and Premack’s (1994) reward identity version, two different food items are hidden under two cups in view of the subject. Then, the cups are hidden from view, and the food item is removed from one of the cups. The removed item is presented to the subject by the experimenter eating it, visibly discarding it, or placing it between the cups. Through reasoning by exclusion, one can conclude that the cup previously containing this item is now empty and that the other cup contains the other kind of reward (Fig. 1). Because two different food types are used, it is crucial that a preference test is also performed to confirm that both rewards are similarly preferred.

This version has provided evidence for reasoning by exclusion in some gorillas, bonobos, chimpanzees, orangutans, and gray parrots, though performance is notably poorer than in the reward location version (Call 2006; Pepperberg et al. 2013; Premack and Premack 1994). For instance, Clark’s nutcrackers excel in the location version, but only one of the six birds was successful in the identity version (Tornick and Gibson 2013). Older great apes performed markedly better than younger ones (Call 2006).

Similar to the location task, the subject may understand that one cup is empty, but is not required to reason about the contents of the remaining cup to be successful. There are two notable attempts at controlling for this weakness. Call (2006) gave gorillas, bonobos, chimpanzees, and orangutans additional association trials using colored chips to test whether subjects can solve the task by learning a conditional discrimination. Subjects first learned an association between the color of a chip and a particular food type. Then, instead of presenting the removed food item to the subjects, the colored chip corresponding with the remaining reward was placed in the middle between the two cups. Thus, the color of the presented chip indicated which of the two hidden food items still remained. Subjects failed to perform above chance in these association trials and also in further experiments where the chips were replaced with two new food items – different from those hidden under the cups – to increase salience of the stimuli. Subjects also failed when a copy of the food type that would be removed was present in the middle throughout the entire trial. Call (2006) reasoned that the consistent failure of the subjects to learn to use a conditional discrimination, compared with their success in the classic inferential task, meant that subjects were likely solving the task through reasoning by exclusion.

A different set of control experiments was designed by Pepperberg et al. (2013) to determine whether African gray parrots used the rule “pick the food item which was not shown.” In these trials, food was placed under the cups as before, but neither was removed. Instead, the experimenter produced another piece of food, identical to one of the hidden items; showed it; and then

removed it again. The birds did not prefer to choose the cup containing the non-displayed food type, which shows their choices were not guided by this conditional rule.

Pepperberg et al. (2013) also introduced trials in which a more and a less preferred food item was used. Instead of a single item, two pieces were hidden under each cup, and only one piece was then removed. Thus, one cup contains two pieces of either the more or less preferable reward, and the other cup contains only one piece of the other type. The reasoning behind this experiment was that the subject would always choose the preferred food item, even in a lower quantity. The task was similar to the regular reward identity task if a piece of the less favorable food item was removed, but subjects should pick the cup containing the revealed item if the more preferable food item was removed. This was assumed to be more likely if the subjects were actively reasoning about the content of both cups, rather than avoiding the empty one. Although all four gray parrots in this experiment passed, their success may be explained by mechanisms other than reasoning by exclusion. Critically, because subjects are shown both food items being hidden, they can simply choose the side where the preferable rewards were hidden and ignore all experimenter manipulations.

## Three Cups Task

### Evenly Spaced

Studies on metacognition often involve a reward hidden under one of three evenly spaced cups (Call and Carpenter 2001; Lambert and Osvath 2020). In an adaptation to investigate reasoning by exclusion, several monkey species were tested with three opaque cups in four conditions (Marsh et al. 2015). Subjects were given either partial negative information (revealing one empty cup), complete negative information (revealing both empty cups), or two types of complete positive information (revealing the baited cup or revealing the baited cup and an empty cup). The complete negative information condition serves as the test for exclusion, as subjects can exclude both empty

options and choose the remainder. The partial negative condition is a control for extraneous cues and discourages the subjects from using avoidance of the empty cup as choosing mechanism. The condition where the baited and an empty cup are revealed is implemented to see whether subjects learned the incorrect rule to “choose the other cup when two cups are lifted.” This study showed that the lion-tailed macaques and hamadryas baboons were able to use exclusion, as well as two out of eight capuchin monkeys.

This evenly spaced three cups task is similar to the reward location two cups task, except that the probability of guessing correctly is lower. For the subject to deduce the location of the reward, both empty cups must in some way be revealed. This results in a similar situation where alternative strategies can be used to obtain the reward. Comparable control conditions are required to narrow down which mechanisms a subject uses to pass these tasks.

### Two Sets

Recently, Pepperberg et al. (2019) used a new method with one of their gray parrots. This method, designed originally for testing children (Mody and Carey 2016), aims to be a more robust test of reasoning by the disjunctive syllogism rather than reasoning by exclusion. The critical difference is that implementing a disjunctive syllogism requires representation of the concepts *or* and *not* – “A or B,” “not A” – as well as deducing the conclusion, “therefore B,” as a *necessity*. This stands in stark contrast with avoiding empty locations, as discussed above, and the strategy where both options are considered independently, as “maybe A, maybe B,” which does not contain this notion of necessity. In this latter non-updating strategy, acquiring new information on the content of one option (“not A”) does not affect the representation of the other option (“maybe B”). In other words, both locations are first seen to possibly contain the reward, and one location is excluded after it is revealed to be empty. The likelihood of the second location being baited does not get updated, yet this second location is still chosen since it is the only *likely* alternative in the two cups

task. Using the disjunctive syllogism means regarding this second location as the *necessary* alternative.

To tease apart these explanations, subjects are first tested on a three cups task (see Fig. 2). Unlike the evenly spaced cups from the previous section, these cups are arranged in two sets: a pair on one side and a single cup on the other side. A small screen covers the view, and a reward is placed in a cup on one side, and the same procedure is

repeated on the other side. The screen covers only one side at a time, making it clearer that a reward is hidden under a non-visible cup rather than in a cup on the visible side. No cup content is revealed in any way. This procedure avoids the aforementioned factors of stimulus enhancement and avoidance of empty cups, but does not require an updating strategy. The reward is guaranteed to be in the single cup, whereas each cup in the other set has a 50% chance of containing a reward.

**Reasoning by Exclusion, Fig. 2** An overview of the three cups (left) and four cups (right) procedure. The star indicates the hiding of the reward, X indicates the cup is shown to be empty, check mark indicates the certain

location of the reward, and question marks indicate uncertainty. Rewards are represented by stars and the downward-pointing arrows show their placement. Image modeled after Mody and Carey (2016)

Similar to 2.5-year-old children, the gray parrot Griffin was able to pass this task (Mody and Carey 2016; Pepperberg et al. 2019).

Additional conditions can be run to further tease apart alternative strategies. For instance, by hiding a reward in the paired cups only, mock-baiting the singleton cup (i.e., showing empty hands and performing the typical baiting procedure), and then revealing the other cup in the pair to be empty, the *avoid empty strategy* would predict that the unrevealed cups will be chosen equally. The *non-updating strategy* leads to always choosing correctly because the probability of the singleton cup being baited was zero from the beginning, and hence, no updating is required upon acquiring new information. Another control test is to bait only the singleton cup and mock-bait one of the paired cups and then again show a paired cup to be empty. This condition can reveal the *empty adjacency strategy* (i.e., choosing the cup next to the one shown to be empty), which is an ineffective strategy here but effective in the two and four cups conditions.

## Four Cups Task

In the four cups task, the cups are again split into two sets, but now, each set consists of two cups (Fig. 2). A reward is hidden under one of the cups in one pair behind a small screen, and the same procedure is repeated on the other side. The screen again covers only one side. Then, the content of one of the empty cups on one side is revealed. Thus, a subject using the disjunctive syllogism now knows that the revealed cup is certainly empty and the paired cup *must* hold a reward, whereas each cup in the other pair *may* hold a reward. In contrast, the three non-revealed cups will be chosen equally often if the subject avoids empty cups or does not update its representation after learning which cup is empty. Not only did Griffin perform above chance in this condition, but also he outperformed 5-year-old children (Mody and Carey 2016; Pepperberg et al. 2019).

The authors point out that Griffin's success could be achieved by picking the cup next to the one that was shown – the *empty adjacency*

*strategy*. They designed two control conditions to circumvent use of this strategy. In the first, called *type 1 gambling* trials, they baited only one pair of cups, mock-baited the other pair, and revealed the content of one of the cups from the non-baited pair. If Griffin was using the previously mentioned rule to decide, he would now incorrectly choose an empty cup. In *type 2 gambling* trials, a more desirable reward was placed in one of the pairs, with the standard reward placed in the other pair from which the empty cup would be revealed. As a result, the desirable reward is a gamble of 50%, whereas the standard reward is guaranteed. Griffin passed the type 1 gambling trials, which shows he did not choose the cup next to an empty one, and his willingness to gamble in the type 2 trials seemed to rely partially on whether he previously gambled correctly – a very recognizable response.

However, the increased diagnostic robustness of the four cups task comes at a cost. First, subjects must have some understanding of underlying probabilities, which has been studied relatively little. For example, while chimpanzees perform well when choosing between two options with large discrepancies in probability, they performed around chance level when these probabilities were 1 and 0.5 for each option – the same ratio as the three cups task with both sets baited (Hanus and Call 2014).

Second, as also pointed out in the initial study of Mody and Carey (2016), the task may have high memory demands because it involves two rewards, four cups and two cups pairs. Pepperberg et al. (2019) proposed this as an explanation for the differences in performance between 2.5- and 5-year-old children and why all performed poorer than Griffin did. According to this hypothesis, the usefulness of this task is limited to animal species that have comparable short-term memory to 3-year-olds, which were the youngest to pass the four cups task.

Third, there remains a risk of obtaining false-positive results. Most notably, the subject's mental representation of the task may resemble that of the two cups task, in which case it would suffer from the same issues. In the initial experiment by Pepperberg et al. (2019), Griffin may only focus

on the cups which are handled by the experimenter and ignore the other set. The type 1 gambling to a degree controls for this. However, the issue with these is that contrary to the standard trials, the subject is shown that only one of the two sets is baited. In these cases, the subject's focus may be on the baited set from the start and would ignore the experimenter's manipulations of the other set.

The four cups task is best suited to reveal the non-updating strategy, for which the other tasks are poorly equipped. It is designed specifically to test for disjunctive syllogism, which requires an updating strategy and then coming to a necessary conclusion of where the reward *must* – rather than *might* – be hidden. It follows that using this stricter definition leads to more conclusive results. Interpretation of the results depends on whether the subject considers there to be four viable choices (every cup) or only two (only the cups on the side that is handled). Various control conditions should be performed to rule out these alternative explanations. To date, Griffin is the only animal that has been tested on the four cups task with controls. However, performance on the four cups task may be limited due to additional cognitive demands – especially short-term memory and probabilistic reasoning. Nonetheless, the four cups task offers an elegant approach that should be further explored in more species.

Table 1 summarizes the various designs of the cups tasks and performance per strategy. The expected performance for each solution per task can be used to determine with what strategy a subject's performance is most consistent. Actual performance is likely lower due to limiting factors such as motivation, attention, inhibitory control, memory, and efficiency. There can be large variation of duration, waiting time, and other aspects of the procedure. Within the same task, subjects may learn or employ multiple strategies; across tasks, their learning may transfer or strategy use can be flexibly adjusted. The most rigorous task would only be solvable by reasoning through a disjunctive syllogism and would predict significantly lower scores when using alternative strategies. Only a combination of multiple tasks has the power to do so, and there are clearly more possible

strategies than the ones discussed here. Furthermore, increasing the complexity of a task carries a higher risk of false negatives. The larger numbers of cups, rewards, sets, and actions of the four cups task demand more attention and better memory than the various versions of the three cups tasks. Thus, these trade-offs need to be considered when planning empirical studies.

## Invisible Displacement

The invisible displacement task is usually not specified as a test for reasoning by exclusion, even though it is. It was originally designed as a test for the concept of object permanence – understanding that objects continue to exist when not perceived – during development in children. This task has since been tested in numerous species, including chimpanzees, bonobos, gorillas, orangutans, dogs, dolphins, Goffin's cockatoos, and gray parrots (see Zewald and Jacobs 2021).

The general setup of invisible displacement tasks consists of multiple opaque hiding locations (e.g., cups or screens) and a smaller opaque displacement device (e.g., a small cup or the experimenter's hand) that is used for moving the reward between locations without being visible to the subject. The experimenter places a reward in the displacement device in full view of the subject. The device is moved behind a hiding location, and the reward may or may not be secretly deposited there. After the reward has been deposited and before moving to the next location, the displacement device is shown to be empty. The observer should choose this location because the reward has been invisibly displaced there. The identity version of the two cups task also involves invisible displacement.

Great apes generally pass invisible displacement tasks (Barth and Call 2006). This does not only attest to their representation of object permanence but also their inference by exclusion, because upon seeing that the displacement device is empty after visiting a hiding location subjects should infer that the reward has been moved from the device to this particular hiding location. In other words, they should represent that the reward

**Reasoning by Exclusion, Table 1** Task properties of key variations of the cups tasks in the visual domain and prevalent solution strategies. Expected performance is shown as a probability of choosing correctly for each solution per task. Task design reflects memory and attention loads as quantified by number of cups, sets, rewards, reward types (preference differences shown in parentheses), baiting actions (placing real or mock rewards and moving or removing the screen), and updating actions (revealing a cup to be empty after screen is removed, except in the reward identity task where the updating action is removal of a reward before the screen is removed). Type 2 gamble

shows the probability of choosing the preferred reward when it is the subject's specific goal; the corresponding probability for the non-preferred reward is shown in parentheses. When a strategy does not apply in a task, the expected probability equals chance level. Not shown are control tasks such as reveal all cups, baited cup, or no cups. An avoid empty and empty adjacency strategies have identical predictions within sets. An empty adjacency strategy across sets would have different predictions depending on the location of the baited cup

| Number of              | Two cups                            |                 | Three cups               |                   | Four cups              |                    |                        |                        |                        |

is either in the device or the hiding location; the reward is not in the device; therefore, the reward is in the hiding location. Because subjects do not see any of the locations being empty, avoidance is not a viable strategy (Völter and Call 2017). However, subjects may instead choose the last or first visited location, depending on the experimental procedure. Moreover, this task cannot test for disjunctive syllogism because subjects are not required to update the possible contents of locations and the device in terms of certainty and uncertainty. Thus, this task suffers from similar weaknesses as the two and three cups tasks.

To explore this issue, Watson et al. (2001) allowed children (4–6 years old) and dogs to search all locations and used search speed as a measure for reasoning. They reasoned that if subjects updated their understanding of the potential contents of the remaining locations after each visit, they should increase the speed at which they check each subsequent location. Instead, if subjects use a general search strategy, each unsuccessful visit would act as an extinction trial – weakening the association between container and reward – which would result in slower visits to subsequent containers. The children showed an increase in speed as predicted by the updating strategy, whereas the dogs slowed down and were thus likely using a general search strategy.

## Bent Tube Task

Instead of cups, bent tubes have also been used to test for reasoning by exclusion. This task was originally used for studies on metacognition, much like the three cups task (Call and Carpenter 2001; Lambert and Osvath 2020). The subject is presented with two tubes, one straight and one bent in an L shape. The tubes are presented in different orientations, which means subjects may or may not be able to look into them from their starting position. This creates three possible locations for the food: in the straight tube, the close end of the bent tube, or the far end of the bent tube (see Fig. 3). Subjects either have full information from the start (3a), can see the straight tube is empty and should therefore be able to reason by exclusion about the location of

the reward (3b), have only partial information but cannot exclude either tube as an option (3c), or have no information at all (3d). This method has been tested with taxa such as great apes, capuchin monkeys, kea, New Caledonian crows, and ravens (Call and Carpenter 2001; Jelbert et al. 2015; Lambert and Osvath 2020; Schloegl et al. 2009; Völter and Call 2017).

In one study, ravens and kea were allowed to freely move around the tubes, so they could inspect them from all sides (Schloegl et al. 2009). The researchers argued that the amount of explorative behavior would depend on the amount of information the animals get from their starting position. For example, with full information, the birds were not expected to explore the tubes. If they were unable to see the reward, they were expected to either explore until they find it or exclude other options to infer the reward's location. Choosing the bent tube after seeing the empty straight tube in the “reasoning” condition is suggestive of reasoning by exclusion. In the no information condition, subjects should choose the baited tube after inspecting only the empty tube. Using these criteria, the authors concluded that the ravens used reasoning by exclusion, whereas the kea did not because of their high number of redundant inspections.

False negatives can arise because searching for the reward may present a less demanding solution than reasoning by exclusion. While more time-consuming, it may be a more natural strategy that will still result in a food reward eventually. This may explain the low prevalence of the “reasoning” strategy in the study of Schloegl et al. (2009), where out of all situations where inference was possible it was only shown between 10% and 25% of trials for ravens (see also Lambert and Osvath 2020). This issue is even more obvious for the kea, which generally opted to investigate all locations. As the authors point out, this is likely a result of the kea being more explorative by nature compared to ravens. It may also be difficult to discern whether a subject moving for a tube has reasoned there must be a reward in it or is heading over to inspect it and happens upon the reward.

A similar setup was used with New Caledonian crows, but here, subjects were not allowed to

**Reasoning by Exclusion, Fig. 3** Schematic overview of common orientations of the bent tube task. The stars indicate the possible locations for food to be hidden for every orientation (note that only one piece of food is hidden per trial). (a) The food is visible. (b) The subject can see the straight tube is empty and should be able to reason that the

reward is in the bent tube (two possible orientations for the bent tube shown). (c) One end of the bent tube is visibly empty, so the reward can be present in either tube. (d) The subject cannot look into any of the openings. All orientations shown are also performed mirrored (i.e., bent tube on the right). (Image modeled after Jelbert et al. 2015)

explore the tubes (Jelbert et al. 2015). Thus, the crows only had the information available from the orientation of the tubes relevant to their starting location. The authors predicted no difference in performance on the first orientation shown in Fig. 3b, but in the second orientation with an end of both tubes visible, they anticipated subjects to perform at chance when using avoidance. They argued that both tubes would appear empty, so the subject would guess or adopt a side bias. If they instead had a mental representation of the whole setup, they could reason the reward is in the third unrevealed location of the bent tube. In the incomplete condition (Fig. 3c), if birds were applying avoidance, they would be expected to avoid the seemingly empty bent tube, while if they were using reasoning by exclusion, they would understand the reward may be in either tube.

Jelbert et al. (2015) acknowledged a potential concern with their setup. The subjects may view the two ends of the bent tube as two different locations, thus essentially turning the task into a

three cups task. This would mean that subjects could be avoiding all visibly empty ends and still reach the performance predicted by reasoning. In the first orientation of Fig. 3b, subjects can then avoid the empty straight tube (“Not A, maybe B and maybe C”), and in the second orientation of Fig. 3b, subjects can avoid the two empty options (“Not A, not B, maybe C”). Moreover, as the bent tube is considered one choice, subjects would succeed even if they can only exclude only one option (“maybe B, maybe C,” with both seen as correct choices). As such, the bent tube task appears to be less conclusive than the three cups task. Jelbert et al. (2015) argued that if subjects viewed the bent tube as two different locations, the birds would approach the bent tube by avoiding the visibly empty side. Instead, they observed that both successful birds approached each side of the tube equally, which they took as supporting evidence that their subjects were indeed using exclusion. This reasoning, however, depends on whether the birds would indeed avoid

passing the visibly empty side on their way to the reward.

Although the bent tube task offers an ecologically relevant approach because it involves various knowledge states when searching for food, it does not provide conclusive evidence for reasoning by exclusion. False positives may arise from avoidance of empty locations. Much like in the two cups task, subjects perceive which of two locations is not baited and can subsequently choose the other option. False negatives are likely caused by inefficient rather than erroneous search behavior. The only cost of looking in all locations is the small delay and extra effort compared to reasoning by exclusion because the reward can always be obtained. Humans fully capable of reasoning by exclusion still behave sub-optimally. This is illustrated by the “passport effect” – repeatedly checking whether one has packed a passport when embarking on international travel. This may seem irrational when one remembers that it is already packed, yet the costs of checking are low, and the potential benefit is high if it was actually forgotten, which makes double-checking a reasonable strategy (Call and Carpenter 2001).

Two-Choice Transfer Tasks

The methods discussed so far involve hidden rewards. In contrast, matching-to-sample (MTS) tasks take a more abstract approach. One example comes from a study with chimpanzees, which were initially taught an association between a symbol and a picture of an item in their environment (Beran and Washburn 2002). They were then presented with the picture and several symbols, of which one matched the picture. The chimpanzees were allowed to choose one of the symbols and were rewarded if they chose the one that matched the picture through their initial association. In some trials, a novel picture (i.e., a picture the subject had not yet learned to associate a symbol with) was presented, followed by a novel symbol among a selection of already associated symbols. To choose correctly, the subjects must exclude all familiar symbols (“not A”) and match the novel option to the novel sample

(“maybe B”). MTS tasks have been done with many species, such as chimpanzees, dogs, seals, sea lions, and pigeons (Völter and Call 2017). However, they are inconclusive because subjects can solve the task by choosing the novel option. MTS tasks have been further adjusted in some studies where subjects are required to assign a property (positive or negative) to a novel stimulus in a forced-choice design. These tasks may in the literature still be referred to as (delayed) MTS or two-choice tasks but lack the presentation of a sample. Similar tasks in word learning are called fast mapping, but this term does not exclude avoidance or reliance on novelty (Völter and Call 2017). Therefore, these tasks are called two-choice transfer tasks here. They have been successfully tested with Goffin’s cockatoos, dogs, kea, and rats (Felipe de Souza and Schmidt 2014; O’Hara et al. 2015, 2016; Zaine et al. 2014).

In an extension of the MTS paradigm, Aust et al. (2008) trained pigeons, dogs, human adults, and children with four positive (S+) and four negative (S−) stimuli using a touch screen. In each trial, an S+ and an S− were presented, and the subject had to choose between them, where only choosing the S+ was rewarded (Fig. 4). Upon having learned this discrimination, some unrewarded transfer trials were intertwined with these training trials, in which the S− stimuli were presented in combination with one of four novel

**Reasoning by Exclusion, Fig. 4** Schematic of the two-choice transfer tasks. Subjects are taught to discriminate between a positive and negative stimulus. In the first transfer task, the known negative is displayed together with a novel stimulus S'. In the second transfer task, the novel S' is displayed together with a more novel S''

stimuli, dubbed  $S'$ . The underlying mechanism for choosing  $S'$  here can be either (1) preference for novelty (neophilia), (2) aversion to the  $S-$  stimuli (avoidance), or (3) reasoning that if  $S-$  is negative,  $S'$  must be positive (reasoning by exclusion). To tease apart which mechanism is used, the experimenters introduced four novel  $S''$  stimuli in a second test series. During these test trials, subjects were presented with the  $S'$  stimuli against the novel  $S''$  stimuli. If subjects passed test 1 due to neophilia, they would likely show a high preference for  $S''$ . If subjects initially chose by avoidance of  $S-$ , it is unlikely that enough aversion for  $S'$  has formed during the previous test trials. Thus, subjects using this technique might be expected to follow no coherent strategy and therefore gamble. Finally, if subjects chose by ascribing a positive value to  $S'$ , they would be expected to continue picking  $S'$ , either through a preference of  $S'$  due to previous inference or through a second instance of ascribing a negative meaning to  $S''$ . Regardless of a second inference, subjects that picked the  $S'$  consistently in test 2 were argued to have used inference in the first test. Here, evidence was found for reasoning by exclusion in dogs and humans, but not pigeons.

The first concern with this task is the possibility of an alternative explanation that combines avoidance and other motivations. Subjects that chose  $S'$  by avoiding  $S-$  in test 1 would likely not have formed a strong preference for  $S'$  as these trials were unrewarded. Choice in the second test may then have been guided by secondary weaker motivations or be chosen at random, because neither stimulus has a value yet. For example, through mild neophobia – not strong enough to overcome aversion of  $S-$  in test 1 – the subjects might choose  $S'$  in test 2, thus appearing to choose based on reasoning by exclusion. Moreover, the incoherent strategy in test 2 predicted by avoidance in test 1 may not only result in gambling but also in adoption of a bias, for example, for the  $S'$  stimuli.

A notable limitation of this method is that it is unsuitable for neophobic and neophilic species, which would avoid or prefer the more novel stimuli regardless of inference capacities. This is comparable to the potential influence of local

enhancement in the cups tasks, where subjects often choose the cup last handled by the experimenter. Exploring and controlling for alternative strategies are crucial in all task variations, even when they appear unlikely at first. For example, Aust et al. (2008) found that their most successful pigeon seemed to choose novel stimuli, despite previous research indicating that pigeons are generally more neophobic.

Finally, each  $S'$  was presented a total of only eight times by the end of test 1, at which point subjects were expected to have remembered each stimulus and applied a positive meaning onto it. Some children expressed difficulty in remembering stimuli and pairings (Aust et al. 2008), which puts into question how well the nonhuman subjects were able to remember the  $S'$  stimuli. Regardless of reasoning by exclusion, subjects might not be capable of remembering previous choices, especially when they are continuously distracted by the training trials given in between. Increasing the amount of test trials, however, increases the risk of creating simple preference or avoidance of  $S'$  as the choosing strategy.

O'Hara et al. (2015) made substantial changes in their experiment with Goffin's cockatoos. Also using a touch screen, subjects were first taught to discriminate between two arbitrary stimuli defined as  $S+$  and  $S-$ . Then, novelty trials were mixed in with these training trials in which the  $S+$  stimulus was shown together with a novel  $S-*$  stimulus, where only the  $S+$  was rewarded. The aim here was to train the subjects to not choose based on neophilia (see Fig. 5). Contrary to Aust et al. (2008), the test trials in this experiment were rewarded if the subject chose correctly. The test trials were (1)  $S+1$  vs  $S-$ , (2)  $S+$  vs  $S-1$ , (3)  $S+1$  vs  $S-2$ , and (4)  $S+2$  vs  $S-1$ , where  $+/-n$  indicates a novel stimulus. Thus, while tests 1 and 2 can be solved through trained avoidance and preference, respectively, tests 3 and 4 would require some form of inference as two novel items are compared. Only correct choices on each of these tasks would imply inference by exclusion. Moreover, they argued that the first attempt at test 2 must also be correct, in order to exclude one-trial learning as the mechanism for test 4. The main response types shown by the

| Test 1                                                                                                                                                                                           | Test 2                                                                                                                                                                                           | Test 3                                                                                                                                                                                            | Test 4                                                                                                                                                                                            |                                       |

**Reasoning by Exclusion, Fig. 5** Schematic of the two-choice task by O’Hara et al. (2015). The top row presents the type of stimuli which were presented to the subjects in each test. Their performance on each test was categorized as one of the processes shown on the right side, i.e., scoring correct on each test (✓) meant the subjects were likely using reasoning by exclusion. Errors (✗) on each test were noted as “bad day,” and every other combination of

errors/correct tests was attributed to preference and/or avoidance to certain stimuli or novelty. “Novelty rule abolishment/reversal” means the subjects initially chose by novelty avoidance but changed their strategy after not being rewarded. Additional strategies were explored in the original study, but not included here. Image modeled after O’Hara et al. (2015)

cockatoos were reasoning by exclusion, one-trial learning, and S–2 avoidance. In a similar study with kea (O’Hara et al. 2016), some subjects received these conditions in the order 1-3-2-4 to test whether reduction in the amount of time between the first and second time S+1 and S–1 were presented improves the performance. This would indicate the subjects had trouble remembering the stimuli, but performance did not differ.

However, it is difficult to distinguish between one-trial learning and reasoning by exclusion in this task. The authors mention one-trial learning after an error only, but subjects may learn to avoid S–1 from guessing correctly in test 2 and thereby succeed in test 4. This would not be distinguishable from reasoning by exclusion. Thus, the strictness of these criteria may cause the performance to be incorrectly classified. Birds that were using reasoning may have fallen into any of the other

categories they proposed, including one-trial learning, simply by making a single mistake.

The two-choice transfer task has also been carried out without a touch screen. In dogs, the stimuli consisted of toys which the subjects had to fetch (Zaine et al. 2014). In an experiment for reasoning by exclusion in rodents, rats were shown different shapes as stimuli, which were projected onto a surface with a hole which they could poke their nose into to get a reward (Felipe de Souza and Schmidt 2014). However, none of these experiments contained a second transfer task. Instead, they implemented only a novelty (S+ vs novel S–) and exclusion test (S– vs novel S+). Thus, these studies lack some of the strength of the previously discussed methods.

In the end, the MTS and two-choice transfer tasks can provide robust evidence of reasoning by exclusion. However, the task requires significant

memory capacity, involving numerous abstract stimuli with initially arbitrary reinforcement values and presented in a single trial with several “distracting” trials in between – which is already difficult for children aged 7.5–10 (Aust et al. 2008). The further alteration of the task by O’Hara et al. (2015) provides a more refined approach but is in turn less forgiving for single errors (i.e., choosing the wrong option within the strategy used by the subject). This strictness may also be a major strength that allows for analysis of strategy per session, which is reasonable given that subjects may use a variety of mechanisms for solving the task throughout testing. The kea’s performance was best predicted by inference by exclusion, which stands in stark contrast with their poor performance in the two cups task (Schloegl et al. 2009). This illustrates how different methods aimed to examine the same ability can lead to highly divergent results in the same species, which highlights the importance of employing multiple methods to reach firmer conclusions.

## Conclusion

A variety of methods have been developed to test whether animals are capable of reasoning by exclusion. The two cups task is the first and most common but is unable to discern whether the results are due to reasoning by exclusion or some other process, such as avoidance of empty cups. The bent tubes and three cups tasks are similar to the two cups task but instead provide a third potential hiding location. These tasks are mainly used in the context of metacognition but have seen some adaptations to test for reasoning by exclusion as well. The three cups task may also be used as a prerequisite for the four cups task. The four cups task is designed to test for the stricter definition of the disjunctive syllogism, which requires *certainty* when choosing. This promising task has to date only been tested in a single animal – the gray parrot Griffin – and it remains to be seen how other species perform in this paradigm. It is likely suited for apes and capuchins, which perform well on the two cups task (Call 2004, 2006; Hill et al. 2011; Premack

and Premack 1994; Völter and Call 2017). Finally, the MTS-like two-choice transfer tasks have provided evidence for reasoning by exclusion in parrots, rats, and dogs (Felipe de Souza and Schmidt 2014; O’Hara et al. 2015, 2016; Zaine et al. 2014). This task has different cognitive demands than the cups tasks, which may explain why results differ strongly even within species. Inferring the cognitive mechanisms in any given task requires mapping the predicted outcomes of prevalent strategies and within-subject testing on multiple variations (Table 1, Fig. 5).

These tasks have to date provided some evidence for reasoning by exclusion in several species. The species tested most are chimpanzees, orangutans, gorillas, capuchin monkeys, dogs, gray parrots, kea, and ravens. While a wider spread of taxa tested in cognitive research is an important step to better understand the evolution of cognition (Lambert et al. 2019), the diversity of methods yielding divergent results makes it more difficult to draw strong conclusions. Instead of asking which species can reason by exclusion, we should clarify the definitions and concepts at the core of this question and refine the methods with suitable controls that reduce the probability of both false negatives and false positives, until we can ask the more productive question to what degree a species can reason by exclusion and work through disjunctive syllogisms.

## Synonyms

### Memory; Recollection

Recall is the act of reproducing information from memory. In psychology, recall often refers specifically to the type of test that requires subjects to reproduce remembered information. Recall is usually characterized as relying primarily on the memory process of recollection, or the detailed retrieval of information from memory. For example, when

you complete a fill-in-the-blank question, you recollect information on a recall test. Although recall and recollection are often used interchangeably, most literature suggests that multiple cognitive processes contribute to performance on recall tests and that recollection contributes to performance on non-recall tests. Recall is most often contrasted with recognition, the act of indicating whether a currently-experienced stimulus was experienced previously. Recognition is usually characterized as relying on a combination of recollection and familiarity, the vague sense of having experienced something before. For example, when you complete a multiple-choice question, you use recollection and the familiarity of each possible answer on a recognition test. The key difference between recall and recognition is whether the possible answers are present when the subject is making their decision.

In humans, recall is usually studied using language. This is primarily because speaking or writing is an easy way for subjects to reproduce word stimuli. For example, a common recall test might have a subject read a list of words, wait through a retention interval, and then be asked to say all words they recollect. Nonverbal recall tests also exist, and these usually require subjects to reproduce a remembered shape by drawing it. For example, tests using the Rey–Osterrieth complex figure require subjects to study a figure composed of various lines, dots, and circles and then draw it on a blank sheet of paper after a delay period (Rey 1941). The defining feature of these recall tests is that they require a generative response.

Because recall tests rely on generative responses such as speaking or drawing, they are rarely used with nonhuman animals. In 1971, Eugene Winograd wrote, “Given the traditional distinctions made between findings based on recall and recognition data, it is intriguing that the question is so inappropriate with animals. . . . Animals, to my knowledge, have not yet been accorded the privilege of having an executive editor rummaging around in a mnemonic file cabinet. They are still denied the power of recollection”. Partially due to our inability to ask nonhuman animals if they recall past information, some researchers have proposed that nonhuman

animals are “stuck in time” and only respond to the needs of the present moment (Suddendorf and Corballis 1997).

Nonetheless, a small body of evidence demonstrates that some nonhuman species can complete generative recall tests, and a larger body of evidence suggests that the ability to recollect information is phylogenetically widespread. For example, rhesus monkeys can reproduce simple shapes on a touchscreen after short retention intervals (Basile and Hampton 2011). Although much simpler, this test parallels human recall tests such as the Rey-Osterrieth complex figure. Similarly, great apes and dogs can reenact observed behaviors after delays (Bjorklund et al. 2002; Fugazza and Miklósi 2014). Outside of these demonstrations of generative recall, there is good evidence from non-recall tests that a variety of species, such as scrub jays, rats, monkeys, and great apes, can recollect information (e.g., Clayton et al. 2003; Eacott and Easton 2007; Guderian et al. 2011). One of the more impressive demonstrations comes from Panzee, a lexigram-trained chimpanzee (Menzel 2005). After seeing food being hidden in an outside forest, Panzee would later spontaneously recruit a caretaker from inside, touch the lexigram corresponding to the hidden food, go outside, and direct the caretaker to the food by pointing to the correct location. Although “Panzee did not literally draw a lexigram or a map of the forest” (Menzel 2005, p. 214), her performance certainly indicates that she would have if she could.

In summary, recall is the act of reproducing information from memory, or the type of memory test that requires a reproductive response. Recall is thought to rely primarily on the memory process of recollection, and it is most often contrasted with recognition. Comparatively, nonhuman animals are rarely given recall tests, but there is decent evidence that many species can recollect information.

## Definition

Any individual who obtains a signal during the communication process.

There are many definitions of a receiver in the communication literature, which vary from a passive individual receiving a signal to one that is more active in obtaining and using that signal. Krebs and Dawkins (1984) provided a more manipulative view of the communicative process. They felt that receivers were “mind readers.” For example, in order for a communicative signal to persist in the environment, it must coevolve with a signaller and a receiver; therefore the mind reader role is that of anticipation and reading of the signaller’s behavior through the signal (Krebs and Dawkins 1984). Zahavi (1975) had a greater focus on the receiver’s side of communication. The handicap principle, which focused on the relative cost of a signal, meant that receivers could not just passively accept or read a signal. Instead, selection required that receivers differentially act on the reliability or honesty of a signal (Zahavi 1975).

The handicap principle is not the only theory to emphasize a more active role of receivers. Morton (1982), in his motivational-structural rules theory, also felt that receivers played a more active role in the communicative process. Morton emphasized that selection cannot, and does not, favor information sharing. Singallers and receivers have very different interests, and thus selection must act on the selfish behavior of each independently in order to a communicative signal to continue. This idea is similar to that of Zahavi’s but places further emphasis on the active role of a receiver. Henessey et al. (1981) further suggested that although manipulation was a good starting point for understanding the communicative process, the receiver (perceiver) faces a different problem than the signaller and as a result will act differently to each signal as it applies to them. The idea of a perceiver, or a more active participant in the communicative process, was further expanded upon by Owings and Morton (1998) and again by Morton (2017). Here the receiver (perceiver) is defined as an individual who is actively perceiving a signal and

differentially acting on it based solely on self-interest. Moreover, perceivers were assessing the signal, in a sense adjusting their behavior to the differing circumstances that the signal communicated (Henessey et al. 1981; Owings and Morton 1998). Expanding on this active role of assessment further Rendall and Owren (2001) expanded on the active role of assessment by receivers, in their affect induction theory. Here receivers are initially affected by the acoustic structure of a signal; in other words certain acoustic features tend to induce attention and arousal and thus initially affect a receiver by garnering their attention. Rendall and Owren (2001) suggest that these types of signals directly affect receiver’s behavior due to their structure and thus result in an appropriate behavioral response for the receiver. They go on to suggest that more indirect effects of signal structure require more learning and assessment on the part of the receiver and that through multiple interactions with particular signals, receivers will come to learn (through basic conditioning) the type of useful behavioral response (Rendall and Owren 2001).

Although these definitions focus on the contributions of acoustic communication to the understanding of receivers, the diversity of the term is portrayed by the research. Further research on the interaction of signaller and receiver in all communicative process will tease apart further the divergent interests of these individuals and broaden our understanding of the receiver’s role.

## Receptivity

Gemma L. Cole  
School of Life and Environmental Sciences,  
Centre for Integrative Ecology, Deakin  
University, Waurn Ponds, VIC, Australia

## Introduction

Receptivity can be defined as the female response necessary to result in successful fertilization by a male. In most species the acceptance that comes from a receptive female is essential to mating; a female has control over sperm transfer and whether it occurs, and nonconsensual mating is generally rare. The onset of sexual receptivity in females is often coordinated with ovarian development and is fundamentally mediated by the production of estrogen in vertebrates (Rissman et al. 1997) and juvenile hormone in insects (Ringo 1996). Receptivity in females is often affected by the quality and persistence of courting males. In many species males will attempt to court the female with nuptial gifts, pheromones and behaviors designed to illicit a sexual response. It is generally accepted that males have constant potential sexual receptivity.

## Receptive Period

The period for which an individual is receptive varies greatly between even closely related species. Some species remain receptive indefinitely whereas some experience very short windows of receptivity, or may only mate once in a lifetime (Beach 1976; Ringo 1996). Receptivity follows a predictable, cyclic, path in many vertebrates (Beach 1976), whereas female invertebrates can be continuously receptive, very briefly receptive, or cyclically receptive and are frequently reluctant to mate (Ringo 1996). Continuous receptivity is generally limited to the invertebrate orders Orthoptera, Hymenoptera, and Heteroptera (Ringo 1996). Receptivity is often highest in virgin individuals and declines rapidly after copulation.

## Signs of Receptivity

Sexually receptive individuals often produce signals that alert potential mates to their reproductive state. Signals of receptivity can be very loosely grouped into two categories: behavioral and non-behavioral cues. These two categories are by no means mutually exclusive and behavioral cues may often be overlooked if they are too subtle for human observers. Nonbehavioral cues can include chemical stimuli such as pheromones, enlargement of sexual features, and color change. For example, chemical stimuli are important in rodents, carnivores, and primates (Reviewed in Beach 1976). Female chimpanzees develop swollen skin to indicate receptivity (Deschner et al. 2004) and females of some fish species change color as an indication of being ready to spawn (Svensson et al. 2009).

Behavioral cues can be much harder to detect. Some, more conspicuous, behavioral displays of female receptivity can be found in female non-human primates and include postures of the body and facial expression such as eye contact (Dixon 1990). Combinations of nonbehavioral and behavioral cues are common where behavior enhances the efficacy of nonbehavioral cues, for example, female Norway rats leave their burrows

at night in order to leave chemical trails for males (reviewed in Beach 1976).

Female signs of receptivity are readily detectable by males. For example, male dogs approach females injected with estrogen more frequently than control bitches (Beach and Merari 1970). Male wolf spiders are able to assess reproductive status and potential receptivity of females using cues from their silk (Roberts and Uetz 2005).

### Male Control of Female Receptivity

Female receptivity is often the key to successful sperm transfer and males can influence the receptivity of females. For example, male mice are able to regulate female reproductive behavior through a specific male pheromone (ESP1) contained in tear fluid (Haga et al. 2010); upon mounting the females, the males are able to enhance female reception allowing for copulation. In some moth species female egg maturation is stimulated by juvenile hormone derived from the accessory gland of the male. In other systems, males are able to influence the receptivity of potential mates through the presentation of nuptial gifts. These “gifts” are frequently used by arthropods with the intention of persuading the female to mate and are made up of food or male secretions that the female consumes.

Reduced female receptivity can also be triggered by males following copulation. Often, the deposition of sperm in the reproductive tract of the female initiates a process that quickly renders the female unreceptive. In some insect species, such as mosquitoes and fruit flies, individuals experience a sudden shift in receptivity termed “post-mating switch” that is mediated by transfer of molecules present in the male’s seminal fluid (Yapici et al. 2008); in extreme cases this unreceptivity is permanent (Ringo 1996). In *Drosophila* species, receptivity can be reduced via the neural stimulus caused by mating, the paragonial gland secretion and the transfer of sperm.

## Introduction

The term “recessive” in genetics is most often used with the alleles. An allele is a form or variation of the gene which can be either dominant or recessive. Each individual, for a particular gene, attains two alleles, one from the mother and the other one from the father. Therefore, in other words for a particular gene, each individual has two alleles. If the effect of one allele is masked by the other one, then the former allele is called as the recessive allele, whereas the latter one is called as the dominant allele (Mimi Biology 2017; The American Heritage® Science Dictionary 2017). In case of a dominant trait, the presence of only one dominant allele can also ensure the phenotype to be dominant and the related genotype to be heterozygous. In order for recessive trait to be expressed, both the alleles for the corresponding trait should be homozygous recessive (The American Heritage® Science Dictionary 2017). It is necessary to understand the recessive and the dominant genes on the molecular level. Broadly, a gene is responsible for coding a protein and this protein can be an enzyme which will catalyze some reaction. In the simplest of the cases, the dominant gene would code for the protein/enzyme that would further catalyze the reaction (Wanjin and Morigen 2015, Genetics/

Reproduction. ScienceNet – Life Science 2017). For example, in case of cystic fibrosis transmembrane conductance regulator gene (CFTR gene), the dominant allele encodes a channel that can efficiently let chloride into and out of the cells contrary to the recessive allele that cannot encode the mentioned protein. As the recessive allele loses its function therefore, this event is also called as loss of function mutation. Therefore, in case of cystic fibrosis, only if an individual gets both the altered copies of the alleles, he would suffer from the disease otherwise even one normal copy of the allele would be enough to do the job.

Sometimes, at the molecular level, a gene can also encode a dominant-negative variant of the protein which would inhibit the functional version of the protein to do its job too. In a different case, sometimes, a gene encoding a protein acquires a mutation which adds up to its function the event thus called as gain of functional mutation. For example, in case of Huntington’s disease, the protein gains a function of clumping together in plaques which can prove disastrous in the brain tissue. A single copy of the mutant protein can perform this function; therefore, this gain of function is a dominant one (Biology stack exchange 2017; Wanjin and Morigen 2015).

## Depiction of Dominant and Recessive Alleles

There are said ways in order to depict the dominant and the recessive alleles. The dominant allele is depicted by the capital letter say “B” and the recessive allele is depicted by a lower case letter say “b.” The following examples of the genetics in different human traits will help in a clear understanding of the topic.

## Ear Lobe Trait in Humans (Cruz-Gonzalez and Lisker 1981; Krampf n.d.)

It is among few traits in human beings which are still unclear in being Mendelian traits or following

polygenic inheritance (Dutta and Ganguly 1965). But for a clear understanding, we would take it as a Mendelian trait in this example. In case of the ear lobe trait, free earlobes are dominant and attached earlobes are recessive. In this example, the dominant allele for the ear lobe trait is being depicted by “E” and the recessive allele is being depicted by “e.” There can be three possibilities for an individual to have a genotype of “EE,” “Ee,” or “ee.”

1. In the first case, if an individual obtains both the dominant alleles for the ear lobe trait from both parents, then that individual will have a free ear lobe phenotypically and the genotype would be “EE.”
2. In the second case, if an individual obtains one dominant allele from either of the parents and other recessive allele from the other parent, the individual although would be carrier for this condition, phenotypically would have free ear lobes. The genotypic condition of the individual will be “Ee.” It can be seen that the presence of one dominant allele (E) has masked the effect of the other recessive allele “e.”
3. In the third case, if an individual obtains both the recessive alleles from both of the parents, then the individual will have attached ear lobes and the genotypic condition would be “ee.” Here, as there is no dominant allele to mask the effect of the recessive allele and it is present in the homozygous condition therefore, the individual has attached ear lobes.

### Lactase Persistence Trait

This is a different condition following the Mendelian Inheritance pattern. Hypolactasia or lactase nonpersistence or lactase deficiency is a condition that is known to be associated with the deficiency of an enzyme called lactase. This deficiency leads to lactose intolerance and primary lactose malabsorption. This condition follows autosomal recessive inheritance pattern. In other words, it can be stated that the individuals having nonpersistent phenotype are homozygous for the recessive

allele and would have received the two copies of a low lactase-activity allele from both their parents, who may be homozygous or at least heterozygous for the allele (Troelsen 2005). This condition can be normalized by the presence of only one dominant allele since lactase persistence behaves as a dominant trait because half levels of lactase activity are sufficient to show significant digestion of lactose (Troelsen 2005; Wang et al. 1998).

### Eye Color

It is a trait that was previously considered to be Mendelian, but new research has shown that it does not follow Mendelian inheritance but follows the polygenic inheritance pattern. In addition to the extent of melanin found in ones iris, the white collagen fibers are responsible for producing different shades of grey, green, and hazel. In general, the most common eye color is brown, followed by blue, grey, and then green. Eye color is a trait that is influenced by multiple genes. As said earlier that a form or variation of gene is an allele. In normal condition, one form of this gene or an allele can lead to brown eyes, whereas the other form can lead to blue eyes. And if both the forms of this gene are present in the genotype of the individual, the resultant would be brown eyes. But as the eye color trait follows polygenic inheritance, the scenario is different than the normal Mendelian type inheritance. In the current case, the dominant allele of brown color has been represented with “B” and the recessive allele with “b.” Each individual carries 2 copies of alleles; therefore, the genotype of that person can be either “BB,” “Bb,” or “bb.” Due to the polygenic inheritance, the “BB” and “Bb” genotype would not solely lead to the brown eyes, but there are chances that green and blue eyes can also occur. Similarly, the recessive genotype “bb” would mostly form the blue-eyed individuals, but there are possibilities of green and brown eyed individuals as well (Liu et al. 2009; Sturm and Larsson 2009).

Some common recessive and dominant traits have been mentioned in Table 1 (Obtained from

**Recessive, Table 1** Table depicting some human traits and their corresponding dominant and recessive variants

| Trait          | Dominant   | Recessive         |
|----------------|------------|-------------------|
| Chin cleft     | No cleft   | Cleft             |
| Hairline       | Widow peak | Straight hairline |
| Eyebrow size   | Broad      | Slender           |
| Eyebrow shape  | Separated  | Joint             |
| Eyelash length | Long       | Short             |
| Dimples        | Dimples    | No dimples        |
| Eye shape      | Almond     | Round             |
| Freckles       | Freckles   | No freckles       |
| Tongue rolling | Roller     | Nonroller         |

[http://faculty.southwest.tn.edu/jiwilliams/human\\_traits.htm](http://faculty.southwest.tn.edu/jiwilliams/human_traits.htm)).

## Recessive Inheritance Pattern

If a trait is recessive, then in order to express the trait both the copies of the allele should be recessive, i.e., the offspring must receive one recessive allele from the mother and the other one from the father. This genotype would be called as homozygous recessive. The recessive inheritance pattern can be explained with the example of Chin cleft which is a Mendelian trait in humans. Here the dominant trait is the cleft chin in contrast to the recessive trait which is the smooth chin. The dominant allele has been mentioned with “S” and the recessive allele has been mentioned with “s.” Individuals having a genotype of “SS” would have a cleft chin, whereas the “ss” genotype individuals will have a smooth chin. The individuals having “Ss” genotype would also show the cleft chin phenotype, but they would be carriers of the recessive allele (Genetics Generations 2015). In order to determine the probability of the inheritance of the smooth chin (or any other recessive trait), the genotypes of the parents must be taken into account. If one parent is heterozygous and has “Ss” genotype and the other is homozygous recessive having “ss” genotype, then the probability of their offspring having recessive genotype or the smooth chin trait can be shown by a Punnett square as shown in Fig. 1.

|   |    |    |
|---|----|----|
|   | S  | S  |
| S | Ss | Ss |
| s | Ss | Ss |

**Recessive, Fig. 1** Figure depicting that with parents having genotypes of “Ss” and “ss,” the chances that the offspring will have a smooth chin is 50%

## Some Common Myths Explained (Learn. Genetics. Genetic Science and Learning Center (n.d.))

### 1. Dominant phenotypes are not always common than the recessive phenotypes

It is well known that two dominant alleles will lead to a dominant phenotype, one dominant and one recessive allele will also lead to a dominant phenotype and two recessive alleles will lead to a recessive phenotype. Therefore, it is a common myth that the possibility of a dominant phenotype in a population is twice that of the recessive phenotype. This is not always correct. In case of eye color, brown color is the dominant phenotype, whereas the blue color is the recessive phenotype. In Scandinavia, blue eyed people (light color) are higher in number than the brown eyed people (dark color). Therefore, the recessive alleles for the eye color in Scandinavia are higher than the dominant alleles.

### 2. Dominant alleles are not better than recessive alleles

It is a common myth that the dominant alleles are better than the recessive alleles. But the truth is that the mode of inheritance has nothing to do with the beneficiary effects of the allele on an individual. For example, rock pocket mice has a gene that controls the fur color. The fur can be of two different colors,

one is dark and the other one is light. The dark fur color is the dominant trait, whereas the light fur color is the recessive trait. When these mice thrive in the habitat where the dark rocks are abundant, then the dominant allele becomes advantageous as it allows the mice to have a dark fur and it can easily mix into the surroundings and escape the predators. Contrary to the above situation if the dark fur mice thrive in the regions of the light colored rocks, they would be easily identified and killed by their predators. Hence, in this kind of environment, the light fur color proves to be advantageous. Therefore, it can be concluded that it is not the inheritance pattern that determines that an allele can be advantageous or disadvantageous for a particular individual, but the environment plays a major role in it.

### 3. A “broken” allele can have a dominant inheritance pattern

Broken alleles/genes here mean those genes that do not perform their normal function. Many genetic disorders involve such kind of genes that produce altered proteins, but the other copy of the protein produced by the normal gene comes to rescue and masks the effect of the broken allele/gene. Henceforth, these kind of genetic disorders follow the recessive inheritance pattern. But the myth that all genetic diseases are recessive in nature is not correct. Keratin proteins are fibrous proteins that have the role in strengthening the hair, fingernails, skin, and other tissues of the body. It is surprising, but the genetic disorders involving the keratin proteins follow mostly dominant inheritance patterns, an example of the same is pachyonychia congenita. This disease is characterized by dystrophic, thickened nails, and painful palmoplantar keratoderma and occurs due to the mutation in one of the four keratin genes (George 2016).

## Conclusion

Each individual possesses genes that encodes proteins and these proteins are involved in some or the other reaction in the body. These genes are

governed by the alleles that an individual acquires from parents. If both the obtained alleles are dominant or if even one of them is dominant in nature, then the gene shows a dominant phenotype and the relevant protein is expressed. But in case both the alleles obtained from the parents are recessive, then the gene would show a recessive phenotype and the relevant protein would not be produced. In other words, it can be said that the recessive traits follow an inheritance pattern in which an individual should be homozygous recessive in order to depict the recessive phenotype. Many examples of the Mendelian traits which have one gene encoding for one trait are available in nature such as chin cleft, dimples, lactase persistence trait, hairline. Many other traits that follow the polygenic mode of inheritance such as eye color give us an understanding that apart from the dominant and the recessive phenotype multiple other intermediate phenotypes can also be available. Furthermore, many myths regarding the genetics of the dominant and the recessive alleles have been discussed in detail so as to provide the readers a clear understanding of the topic.

## Synonyms

- [Recombinant inbred lines](#)

## Definition

A recombinant inbred strain is a strain formed by crossing two inbred strain, which is continued to be crossed or say repeated for the next 20 generations.

## Introduction

Recombinant inbred strains (RIS) are the offspring developed from the two foremost inbred lines, which contains approximately the same ratio of genetic contributions of their ancestors. The repeated crossing is strictly done between brother x sister to form a new inbred line; this leads to the construction of a genome which is mosaic of the genome of the parents.

In this way production of a line is done which has unique property but is related to one another. It can also be understood as when different parents which were inbred meant as members of a set.

These organisms undergo important recombination events in their chromosomes, which they inherit from more than two inbred lines.

Recombinant inbred strains are produced by combination of selfing progeny of individual members of an F2 generation until complete homozygous achieved.

It also equalizes marker type like double haploids; the genetic segregation ratio for both dominant and codominant marker would be 1:1.

They are also crucial and useful in identifying tightly linked markers when obtained after several cycles of meiosis (Adamová et al. 2018).

## Discovery

Mainly, recombinant inbred strains of mouse produced during the 1950s. Dr. Donald Bailey made other scientists understand the importance of these genetic constructs. He conceptualized its usage for linkage analysis. As these recombinant strains provided a promising alternative to the lengthy procedure of classical breeding analysis which was required generally to map the uncovered locus.

Dr. Bailey first made eight recombinant inbred strain set – the original CXB set – and moved it to Jackson Laboratory in 1967. In the year 1969, along with Dr. B. Taylor, he took up the cause of the recombinant inbred approach and set about, developing from several pairs of progenitor parents, large sets of recombinant strain that are now standards for mouse genetics communities including BXD, BXH, ARXL, and AKXD.

The recombinant inbred strain is used to map mouse genes and helps in the study of other experimental organisms such as the plant *Arabidopsis thaliana* (Bailey 1981).

## Taxonomy

Recombinant inbred strain should be designated by uppercase one- or two-letter abbreviation of both parental names, with the female strain written first and separated by an uppercase letter X with no intervening spaces (e.g., HXB1,

HXB2, HXB3; members of the HXB set of recombinant inbred strains consequent from a cross of SHR/OlaIpcv x BN-Lx/Cub) (Pollard 2012).

## Usage

Rat and mouse recombinant inbred strains (RIS) provide powerful tools for genetic mapping. These include the following: genotyping of each strain is required only once; multiple individuals from each strain may be phenotyped to reduce individual, environmental, and measurement variability; multiple phenotypes can be assessed on the same genetic background. Also, as recombination events are denser in RIS than those occurring in any one meiosis, higher mapping resolution can be achieved (Silver 2001).

## Advantages

1. Each strain is an everlasting resource as the study of multiple phenotypes is possible with the same genotype.
2. For any study, a strain is needed to be genotyped only once.
3. Individual variations are reduced, utilizing phenotyping several individuals from each strain.
4. These recombinant strains are immortal lines. They are replicated over years and years at several locations and hence are of prime importance in producing quantitative trait loci.

## Conclusion

Recombinant inbred strains are a vital resource for intricate mapping traits in various species. Inbred lines are already made majorly for experimental species like *Arabidopsis*, mouse, *Drosophila*, and *C. elegans*. It serves excellently for the analysis of epistatic interaction. It is also a powerful mechanism for analysis of gene function and quantitative traits, which is useful in studying proteome data sets under a variety of environments.

## Synonyms

[Alteration](#); [Combination](#); [Modification](#)

## Definition

Genetic recombination is a process which recombines the alleles of two parental DNA molecules or different segments of same DNA molecule and produces new combinations of alleles in the recombined DNA with features not present in either of the parents. Recombination can be observed when sequences are homologous region of chromosomes or when some extent of sequence similarity is present. This process is performed by both prokaryotic cells and eukaryotic cells.

## Functions of Genetic Recombination

Each organism has remarkable potential to sustain in the environment over an extent of time. Genetic variation or genetic diversity allows organisms to evolve in this changing environment and in addition maintain a vast quantity of genetic information. The rearrangement of genetic information is performed by the genetic recombination. Apart from genetic diversity, recombination is also required in double-stranded DNA breaks repairing and during DNA replication for gaps filling and for preventing replication fork stalling (Li and Heyer 2008).

## Models of Recombination

On the basis of type of initial DNA break (single stranded or double stranded), the recombination model can follow two pathways, but important steps involved in homologous recombination model are similar in both pathways like homologous DNA strands alignment, breakage of strands, exchange between the strands, and final sealing of the recombined strands (West 1992).

## Holiday Model (Single Strand Break Model)

The holiday model is also known as hetroduplex model as the final recombined double stranded DNA molecule is derived from two homologous chromosomes. Recombination event starts with the alignment of homologous chromosomes. Then a nick is introduced in one of the DNA strand of both the homologous chromosomes at same position. The produced nicked strands invade the opposite complimentary strands by the process called strand invasion resulting in hetroduplex formation followed by sealing of gaps by DNA ligase forming a crossover structure called Holiday junction. Holliday junction is dynamic in nature and migrate laterally resulting in the formation of recombined DNA strands by exchange of DNA strands between homologous chromosomes. Subsequently, the resolution of the

recombined DNA molecules is performed by cleavage across the branch point in two ways producing two different results. If invading strands were cleaved and rejoined then the separated products will be two nonrecombinant molecules. On the other hand, if noninvading strands were cleaved and joined then the products will be reciprocally recombined DNA molecules. Holliday model does not explain how single strand nicks are produced at equivalent positions in each helix. Hence, Meselson-Radding modification proposes the initiation of recombination by

single strand break in DNA strand of only one of the homologous chromosomes (West 1992) (Fig. 1).

**Double strand break model:**

This model is similar to the Holliday model except that the initial break is a double strand nick in one of the two homologous chromosomes. Exonuclease trims from the 5' end of the nicked region producing 3'-OH overhangs. Only one overhang then invades the opposite duplex and this procedure is called single strand invasion. Elongation of the strands from the 3' ends using opposite homologous chromosome as a template result in the formation of two Holliday junctions (Haber et al. 2004).

**A. Homologous recombination**

**B. Non-Homologous recombination**

**C. Site specific recombination**

**D. Replicative recombination**

**Recombination, Fig. 1** Types of natural recombination. Single line represents double stranded DNA. (a) Homologous or general recombination. (b) Nonhomologous

(or illegitimate) recombination (c) Site-specific recombination and (d) Replicative recombination

## Enzymes Involved in Recombination

The steps involved in homologous recombination were first described in bacterial system (Clark 1973) and the well-identified recombination system is RecBCD. RecBCD enzyme is also known as exonuclease V and is a protein complex of three different subunits called RecB, RecC, and RecD.

The RecB subunit has nuclease and 3′–5′ helicase activity and RecD has 5′–3′ helicase activity. RecC is involved in chi site recognition while RecA has property to coat DNA fragment and invade the double helix. Branch migration is performed by RuvA and RuvB protein complex and lastly RuvC protein catalyzes the cleavage step that resolves the Holliday structure. In eukaryotic system, the recombination event has been explored in the budding yeast *Saccharomyces cerevisiae*.

## Types of Recombination

Recombination has been classified into four types in different organisms.

### 1. General or homologous Recombination

Homologous recombination is performed during meiosis in eukaryotes and involves alignment of homologous chromosomes with similar DNA sequence. Chiasma is the site of crossing over between the two chromatids of the homologous chromosomes which allows recombination of the genes between the homologous chromosomes (Sung and Klein 2006).

General recombination can be further classified into reciprocal recombination and non-reciprocal recombination (gene conversion).

- (a) Reciprocal recombination involves even exchange of genetic material between the homologous chromosomes. For example, homologous recombination between A and B genes of two homologous chromosomes A+B+C+ and A–B–C– results in recombined products A–B+C+ and A+B–C–.

- (b) Nonreciprocal recombination is also known as gene conversion. Nonreciprocal recombination occurs when genes are transferred from one sister chromatid to the other chromatid, but no reciprocal exchange of genetic information occurs. For example, homologous recombination between two homologous chromosomes A+B+C+ and A–B–C– will produce new recombined products A+B+C+ and A–B+C– with one of the parental chromosome remained unchanged.

### 2. Illegitimate or nonhomologous recombination:

Nonhomologous recombination requires only little sequence similarity between the DNA segments. Joining the broken DNA ends and DNA replication errors are the main sources for the occurrence of nonhomologous recombination event. Examples for non-homologous recombination are deletions and translocations of the DNA segments.

### 3. Site specific recombination:

Unlike homologous recombination, site specific recombination does not require extensive DNA homology sequence for recombination. Site specific recombination occurs between short (about 12–24 bp) and specific region DNA. It also requires specific recombination enzymes. Site specific recombination is performed using two types of mechanisms (Grindley et al. 2006).

- (a). Transpositional site-specific recombination: Transpositional site-specific recombination does not require specific sequence homology and thus no heteroduplex formation occurs.
- (b). Conservative site-specific recombination: Conservative site-specific recombination requires short sequence similar between the two DNA molecules and also involves formation of a short heteroduplex.

### 4. Replicative recombination:

Replicative recombination is a process performed by many transposable elements in which a new copy of a DNA segment is generated at a new location.

### 5. Mitotic recombination:

Mitotic recombination takes place during interphase i.e. the resting phase between mitotic divisions. Mitotic

recombination is a rare phenomenon and is similar to the meiotic recombination.

Most of the prokaryotic organisms have asexual reproduction and possess only one set of chromosomes while organisms participating in sexual reproduction have two sets of chromosomes which increases the genetic diversity in them. However, prokaryotic organisms also increase genetic diversity by different molecular mechanisms like conjugation, transduction and transformation (Carpa 2010). Recombination has similar functions in prokaryotic cells like DNA repair and replication as observed in eukaryotic cells.

1. **Conjugation:** Conjugation based recombination involves physical contact between donor and recipient cells. Donor cell transfers the single strand of DNA from F-plasmid (not present in recipient cells) to the recipient cell via a bridge-like structure called pilus.
2. **Transduction:** The transfer of genetic material between the cells occurs through virus or bacteriophage. When virus infects the bacteria, it exploits the host machinery for its replication and breaks down host DNA. Host DNA gets packaged into few of the phages envelop forming transducing phages. After lysis of the donor cells, both normal phages and the host DNA containing transducing phages release out. If transducing phage infects recipient cells, it will introduce donor DNA inside the recipient cell which can get incorporated in the genome of recipient cells via recombination.
3. **Transformation:** Some species of bacteria can take up the naked DNA from the surrounding and incorporate them into their genome. This process is called natural transformation. Many bacteria are not competent in nature and therefore many methods are used (electrophoresis, calcium chloride treatment) to increase their competency for transformation.

## Conclusion

Genetic recombination is a well-studied mechanism responsible for providing genetic diversity in

eukaryotic and prokaryotic cells. It has other functions like in DNA repair and replication. The mechanism of homologous recombination is well known in both eukaryotic and prokaryotic cells. Prokaryotic cells also perform recombination mechanisms via conjugation, transduction, and transformation.

## Reconciliation

Teresa Romero  
School of Live Sciences, University of Lincoln,  
Lincoln, UK

## Synonyms

[Postconflict affiliation](#)

## Definition

Postconflict friendly reunions between former opponents soon after the end of an agonistic conflict.

## Introduction

Although aggression is not an inevitable outcome of conflict of interest, and social animals have a number of possible options to manage it (e.g., avoidance or increasing tolerance, de Waal 1996), individuals may use aggression as a negotiation tool (Aureli et al. 2002). For instance, animals may threat and attack group mates to gain access to a contested resource or to establish or reinforce dominance relationships. However, aggression is energetically costly and can result in injury, which can entail tremendous costs through infection and disability. For gregarious animals, aggression may also entail other less obvious costs. Observational and experimental data from various primate and nonprimate species show that opponents who have just fought are less tolerant to one another and are also more likely to be involved in renewed attacks after the original conflict has ended (Romero and Aureli 2017). Not being able to approach and interact with a former opponent may compromise the cooperative aspects of the relationship, which in turn may have important fitness consequences for social animals, since the maintenance of stable social bonds positively affect individuals' competitive success and reproductive performance (Seyfarth and Cheney 2012). Once aggression erupts, one or more of these costs are inevitable.

Accumulated evidence from studies on wild and captive populations shows that social animals use an array of behavioral mechanism to mitigate the costs of aggression, generally labeled as conflict resolution mechanisms (Arnold et al. 2010; Aureli and de Waal 2000). Among them, reconciliation – i.e., a friendly reunion of former opponents shortly after the end of a conflict – is probably the most efficient one, since it involves direct communication between involved individuals.

## Occurrence of Reconciliation

Reconciliation was first described by de Waal and Roosmalen (1979) in a zoo colony of chimpanzees (*Pan troglodytes*) in the Netherlands. Since this pioneering study (see de Waal 2000 for a historical review on earlier descriptive accounts), systematic studies in more than 30 species of primates and a number of nonprimate species have shown that affiliative interactions between former opponents occur sooner after the cease of aggression than during control periods, suggesting that reconciliation is a widespread phenomenon among social species (reviewed in Arnold et al. 2010; Aureli et al. 2002; Romero and Aureli 2017). Furthermore, the fact that reconciliation is present in phylogenetically distant species, such as primates, carnivores, cetaceans, birds, or fish, also suggest that this conflict resolution mechanism must have evolved independently several times due to selection pressures associated with living in groups (Schino 2000). The scarce relevant data on nonprimate species, though, does not allow us to know whether reconciliation is a general phenomenon in group living species or, on the contrary, whether it has evolved in only a fraction of social species (Schino 2000).

The majority of research on reconciliation has been conducted in captive populations (76% of all studies), where space is often limited and the avoidance of a former opponent may not be possible. However, a number of studies have demonstrated that reconciliation is not an artefact of captivity, since this postconflict behavior has been observed in populations living in large enclosures (de Waal and van Roosmalen 1979) where prolonged avoidance was possible, and in wild populations, where the option to leave the group, at least temporarily, was available (Silk et al. 1996; Watts 1995).

In most species, reconciliation occurs soon after the end of the aggressive conflict, typically within the first few minutes of the postconflict period (Arnold et al. 2010). However, the type of affiliative behavior that opponents exchange is highly variable. While for some species merely staying in physical contact or in close proximity to

a former opponent may be sufficient to reconcile, other species may use highly differentiated behavioral signals, such as kissing and embracing in chimpanzees (de Waal and van Roosmalen 1979; Fraser and Aureli 2008; Romero et al. 2010), that are rarely observed outside the conciliatory context (i.e., explicit reconciliation, de Waal 1993). This interspecific variation in reconciliation style has been attributed to variation in the average quality of social relationships among species, with high levels of affiliation or tolerance being associated with the occurrence of explicit conciliatory behaviors (Aureli et al. 2002; Thierry et al. 2008).

Variation in conciliatory patterns has also been observed within species. For instance, not all chimpanzee populations use explicit gestures to reconcile, and when they have used these highly differentiated behavioral signals they only represent a proportion of all friendly reunions observed during the postconflict period (Fraser and Aureli 2008). Thus, it is possible that individuals use different behaviors to reconcile depending on their relationship with the opponent or the characteristics of the previous conflict. For instance, individuals may use noncontact behaviors, certain types of vocalizations or facial expression as a less risky conciliatory strategy than directly approaching a former opponent (Schino and Marini 2011). It is also possible that variation on conciliatory patterns is associated with individual behavioral plasticity. However, too few studies are available to draw conclusions about the sources of variation in conciliatory patterns.

Some studies have examined whether aggressors or recipients of aggression are more likely to initiate the affiliative reunion (Arnold et al. 2010). Individual's motivation to initiate the reconciliation should depend on a number of factors. Because of the asymmetric nature of aggressive interactions, the cost of aggression is likely to differ between the recipient of aggression and the aggressor. Also, most relationships are asymmetrical to some extent, and one party may have more to gain from the postconflict contact than the other (Cords and Aureli 2000). In addition, there are methodological difficulties in detecting genuine attempts to reconcile, or subtle conciliatory

signals, such as changes in body posture or facial expression (e.g. Silk et al. 1996). Thus, it is not surprising that findings are inconsistent across studies examining whether aggressors or recipient of aggression are more likely to initiate reconciliation (Arnold et al. 2010). However, the majority of studies that have considered the identities of the initiator of reconciliation regardless of their role during the previous conflict have found that individuals that tend to take the initiative to reconcile are also primarily responsible for friendly contacts outside the postconflict period (Arnold et al. 2010).

## Function of Reconciliation

Reconciliation is a heuristic term that implies the specific function of relationship repair, that is, the restoration of the usual pattern of interactions among former opponents (Arnold et al. 2010; Romero and Aureli 2017, see Aureli et al. 2012 for discussion on alternative interpretations). It should be noted that despite the widely use of the functionally loaded term reconciliation, very few studies have investigated the consequences of these postconflict friendly reunions. The functional analysis of these interactions is extremely important since the occurrence of similar behaviors under similar contexts does not necessarily warrant that the function of such behaviors is the same. In other words, although reconciliation may be a phenomenon common to many social species, its proximate mechanisms and short-term consequences may differ widely.

Studies that have investigated the function of reconciliation show that these friendly reunions serve to reduce the cost of aggression and to restore opponents' relationship. For instance, the occurrence of an affiliative interaction between contestants reduces their probability of receiving postconflict attacks from both former opponents and other group members, which otherwise are higher than baseline rates (Arnold et al. 2010; Romero and Aureli 2017). Furthermore, the usual interaction patterns between former opponents, measured by approaches, time spent in proximity, and affiliation, are lower than baseline

after a conflict, and restored to usual levels once reconciliation takes place (Arnold et al. 2010; Romero and Aureli 2017).

By reducing the risk of renewed aggression and restoring the opponents' tolerance levels, the occurrence of reconciliation also reduces the uncertainty about the postconflict situation, which in turn alleviates the postconflict distress experienced by both opponents. Using self-directed behaviors, such as self-grooming in mammals or self-preening in birds, as noninvasive indicators of anxiety and distress responses (Aureli and Smucny 2000) a number of studies have shown that both opponents may experience high levels of anxiety following agonistic conflicts (e.g. victims: Aureli and van Schaik 1991; aggressors: Romero et al. 2009). Rates of self-directed behaviors in one or both opponents are lower if they reconcile than when they do not (Romero and Aureli 2017). Moreover, the few studies examining physiological responses during the postconflict period bring further support to the behavioral evidence. Cortisol levels in children (Butovskaya 2008) and heart rate in rhesus macaques (Aureli and Smucny 2000) decrease to baseline levels after reconciliation compared to unaffiliated postconflict periods.

Given that reconciliation repairs the relationship between opponents, this conflict resolution mechanism is not only functionally relevant for animals that maintain long-term relationships with conspecifics, but it is also relevant for any species relying on cooperative relationships. The only reported case of interspecific reconciliation between cleaner fish (*Labroides dimidiatus*) and client fish supports this idea (Bshary and Würth 2001).

Despite the widespread occurrence of reconciliation among social animals and its beneficial consequences, reconciliation does not occur after every conflict. Characteristics of the previous conflict, opponents' age-sex class, or matting seasonality can affect the occurrence of reconciliation, at least in some species (e.g. Palagi et al. 2005). However, the factor that most consistently has been reported to determine the occurrence of reconciliation across studies is the quality of the relationship between former opponents (Arnold

et al. 2010). The valuable relationship hypothesis (de Waal and Aureli 1997) predicts that if reconciliation restores the relationship between opponents it should occur more frequently after aggression between individuals that maintain more valuable relationships since they have more to lose if they do not repair the relationship. Supporting this hypothesis, high baseline levels of positive social interactions in primates, canids, or corvids – such as grooming, agonistic support, close spatial association, or food sharing – are typically associated with higher rates of reconciliation (Arnold et al. 2010; Romero and Aureli 2017). Although the name of the hypothesis refers to the value of the relationship, other components of the relationship, such as compatibility (i.e., the general tenor of social interactions in a dyad) or security (i.e., the perceived probability that the relationship with the partner will change; Cords and Aureli 2000) are also expected to determine whether contestants reconcile their conflicts. These latter components of the relationship, however, have received much less attention.

Although the valuable relationship hypothesis relates the variation in reconciliation to the benefits associated with the occurrence of the postconflict reunion – and therefore proposes a possible ultimate explanation – it does not imply that opponents are motivated to reconcile by anticipated benefits or that they are conscious of the long-term outcome of their actions. Such assessments require memory and computational skills that may exceed the cognitive capacities of nonhuman animals, including primates (Aureli et al. 2012). It has been proposed that animals may be able to assess the postconflict situation and modify their behavior according to the quality of the relationship with their opponents by using a much lower cognitively demanding mechanism, such as emotional mediation in the form of postconflict anxiety. The Integrated Hypothesis (Aureli 1997) suggests that the higher the value of the relationship between opponents, the higher the postconflict anxiety should be, as the loss of benefits is greater. This hypothesis thus provides a link between the function and the possible proximate mechanism of reconciliation. Supporting this hypothesis, in some species of primates, the

recipients of aggression and aggressors show both increased postconflict anxiety and higher conciliatory tendencies after conflicts with individuals with which they shared strong affiliative bonds than after conflicts with other individuals (Aureli 1997; Kutsukake and Castles 2001; Romero et al. 2009); but see McFarland and Majolo 2011). Importantly, in none of these studies, the risk of renewed aggression varies with the quality of opponent's relationship (Aureli 1997; Kutsukake and Castles 2001), Romero, *unpubl. data*) suggesting that higher levels of anxiety are due mainly to the damage that the conflict causes more valuable relationships.

An additional, yet largely unexplored, factor that may also explain part of the observed variation in the occurrence of reconciliation is the presence of stable individual differences in behavior, also referred as personality traits (e.g., Sih et al. 2004). Although often less intuitive to approach the study of sociality from the individual level of analysis, cumulative evidence shows that individual differences significantly influence how social processes themselves unfold (Seyfarth and Cheney 2012). Recent work on chimpanzees shows that beyond relationship value, stable individual differences represent a meaningful source of variation in conciliatory tendency, with subjects' conciliatory tendency being consistent across years and situations (Webb et al. 2014).

## Conclusions

More than three decades ago, a pioneering work described how two chimpanzees kissed and embraced to reconcile a conflict. There is now substantial evidence that reconciliation is a widespread conflict resolution mechanism among social species, and that animals reconcile their conflicts in a flexible way. Only a minority of studies, however, have examined the function of reconciliation. This is certainly a shortcoming, as reconciliation may function differently in different species under different conditions. Therefore, the next generation of studies on reconciliation should focus on the functional aspects of reconciliation in a wide range of primate and non-primate species. Another aspect that should

receive more attention is the role of individual differences in reconciliation, since these studies could help us gain a complete understanding of the adaptive consequences of conflict resolution behaviors. Also, we know very little about the development of conciliatory skills. A parallel development of social competence and conflict resolution skills is likely, although no previous research has addressed this topic. Future studies focusing on these topics will help us to develop a more comprehensive framework for reconciliation in animals.

## Red Queen Effect, The

Gavin Vance<sup>1</sup> and Todd K. Shackelford<sup>2</sup>

<sup>1</sup>Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Psychology, Oakland University, Rochester, MI, USA

The Red Queen Effect or Red Queen Hypothesis is a term coined by Leigh Van Valen (1973) to explain the ever-changing nature of evolution by natural selection. The hypothesis states that the likelihood of extinction for any given species remains relatively constant over time. Although a species in a given environment may have an

advantage at one point in time, this places selective pressure on neighboring species who are themselves constantly evolving. Over evolutionary time, no one species maintains a long-term net advantage because other species that inhabit the same environment will evolve counteradaptations. The term is a reference to Lewis Carroll's *Through the Looking-Glass*:

"Now, here, you see, it takes all the running you can do to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!" (Carroll 1982, p. 104).

## Interspecies Competition

Red Queen effects are exemplified in competition between species, such as the relationships between predators and prey. At any one point in time, predators in a given environment seem well-adapted to catch their preferred prey species, whereas prey seem to be similarly well-adapted to avoid being captured and eaten (Angerbjorn et al. 1999). Over evolutionary time, predator species evolve adaptations that improve their ability to capture prey, whereas prey species evolve adaptations to better avoid capture. A similar dynamic exists in parasitic relationships, wherein parasites are adapted to infect their preferred host species, and host species are adapted to defend against parasites (Brun et al. 1992). A less direct form of interspecies competition exists when two species compete to fill a single ecological niche. For example, if two species occupied the same environment and had similar diets, one species might evolve adaptations either to consume a more diverse range of foods or to outcompete the rival species for the contested food.

## Intersexual Competition

The Red Queen Hypothesis can also be applied to opposite-sex members of the same species, as males and females of the same species often have conflicting interests. For example, males have a lower minimum obligatory parental investment required relative to females (Trivers 1972). As a result, males are less discriminating when selecting

sexual partners and have adaptations that facilitate maximizing the number of sexual partners. Females, in contrast, are more selective when choosing sexual partners, prioritize mate quality over quantity, and often evolve preferences for physical cues to fitness. Males also sometimes have adaptations that increase their ability to circumvent female mate choice by gaining sexual access via force or coercion (Bisazza et al. 2001). In response, females evolve adaptations that guard against coercive sexual advances.

## Intraspecies Competition

The Red Queen Hypothesis can also be useful for understanding individual competition between same-sex members of a species. Same-sex individuals of a given species often compete with one another for access to food and mating opportunities. Individuals of some species may even be said to have different strategies, whereby some individuals possess more vibrant physical characteristics that confer an advantage in sexual competition, but a disadvantage in terms of survival. Intrasexual competition over evolutionary time may also result in more exaggerated physical characteristics used to attract mates (Loyau et al. 2005) or better weaponry for competing with same-sex rivals (Robinson et al. 2006). An individual member of a species born with a genetic mutation resulting in a comparative advantage in attracting sexual partners may have an edge in his or her generation. However, such a mutation would be passed down to subsequent generations, eventually becoming a characteristic feature of the species, at which point the mutation could no longer be said to confer an advantage to any one member of the species. Over time, intraspecies competition for resources and mating partners drives the evolution of adaptations to outcompete conspecifics in much the same way that adaptations result from interspecies and intersexual competition.

## Introduction

To set the stage for writing about reductionism, it may help first to review briefly the history of philosophy associated with, as it was known historically, the mind-body problem. However, mind-brain will be used here instead of mind-body. The four basic views are diagrammatically summarized in Fig. 1.

As may be seen in Fig. 1, there are two forms of monism, namely, either the brain alone exists (Thomas Hobbes's Materialistic Monism) or the mind alone exists (George Berkeley's idealistic monism, where *idea* not *ideal* is the root word). There are also two forms of dualism where both the mind and the brain exist. With dualism the question becomes that of how they relate to each other. Descartes believed that both the mind and brain exist, and they interact at the conarium (pineal gland). He also believed that the brain was material and had a boundary and that the mind was immaterial and had no boundaries; it permeated the universe. This form of dualism was known as interactionism. Gottfried Wilhelm Leibnitz believed that the mind and brain both existed independently and that they functioned in perfect parallel, a view known as parallelism.

There is no way to prove the truth or falsity of any of these positions regarding the mind and the brain. All that one can do is choose the one that is most useful or most comfortable personally. Many behavioral scientists are clearly materialistic monists, but many others write in ways that indicate that they are mind-brain dualists. This writer believes that science functions best with materialistic monism, and he cannot in good conscience write about any of the other viewpoints.

Returning to reductionism, two sources were examined for contemporary definitions of reductionism, *The Oxford Guide: Philosophy* (T. Honderich, Editor, 2005) and Turner's (1967) *Philosophy and the Science of Behavior*. The *Oxford Guide* included five definitions pertaining to reductionism by three authors, and Turner provided four definitions. One of the five in the *Oxford Guide* had minimal, if any, relevance for animal cognition and behavior, and it will not be considered further here.

Explicitly or implicitly, the eight definitions emphasized material reductionism. The following

**Reductionism, Fig. 1** Diagrammatic representation of the mind-brain relationship problem

selected portions of the eight definitions are quoted to validate this conclusion.

**Ontological reductionism** (Ruse 2005, p. 793):  
*"All organisms are reducible ultimately to molecules," but often the claim is meant in the more metaphysical sense that there is but one substance or "world stuff" and that this is material.*

**Methodological reductionism** (Ruse 2005, p. 793): *The best scientific strategy is always to attempt explanation in terms of ever more minute entities. It has undoubtedly been the mark of some of science's greatest successes and not just in physics.*

**Theory reductionism** (Ruse 2005, p. 793): *Theory reductionism raises the question of the relationship between theories in a field, as between Newton's theory and that of Einstein. [Given the examples from physics, material reductionism is implicit.]*

**Reductionism, mental** (Kim 2005, p. 794): *Reductionism in philosophy of mind is the claim that facts about mentality are reducible to physical facts, i.e., facts about matter and material processes.*

**Constructual reduction** (Turner 1967, p. 302):  
*The existential status of an object derives from it being empirically real and not inferred.*

**Theoretic reductionism** (Turner 1967, p. 304): *The laws of the reduced science are hereby explained by the laws of the reducing science [e.g., behavioral science is reduced to physiology].*

**Methodological reductionism** (Turner 1967, p. 309): *For psychology, this would mean restricting its theoretical constructs to terms in principle to the language of physiology.*

**Metaphysical reductionism** (Turner 1967, p. 309): *It asserts that for psychology ultimately all questions of theory are to be resolved by physiological reductionism.... This compares with a metaphysical behaviorism which assumes all sentences in the mental language are really translatable into sentences in the physicalistic language; the language presumably of pure mental content is meaningless.*

Of course, there are those who may accept material reduction in principle but who believe one can be a good scientist and work, for example, only at the behavioral level. B. F. Skinner was a

good example of this type of behavioral scientist, and he will be considered further below.

In a material reduction scheme, where is behavioral science among the social, biological, and physical sciences? To illustrate the answer, the down arrow symbol “↓” means “reduces to”:

## Limitations of Measurement that Affect All Sciences

It is important to recognize that, regardless of reductionism, all sciences are affected by limitations of measurement and that reductionism itself can contribute to such limitations (see Figure Legend and discussion associated with Fig. 4 later in this entry). Werner Heisenberg (1901–1976) is well remembered for showing that precise measurement of the position *and* momentum of atomic particles cannot be done. This became known as the uncertainty or indeterminacy principle. Later, Heisenberg (2007) was clear in his *Physics and Philosophy: The Revolution in Modern Science* that the uncertainty/indeterminacy principle was not limited to quantum physics; see, especially, chapter “The Relation of Quantum Theory to Other Parts of Natural Science.” He mentioned psychology but was less clear how his principle applied to “psychological phenomena” except with reference to the brain. However, 13 years before Heisenberg (2007), London (1945, p. 162) had written:

It is the purpose of this paper to demonstrate that the principle of indeterminacy as formulated for quantum theory is grossly inapplicable for psychology and that, in consequence, no matter what may be the

arguments in defense of the statistical approach to psychological problems, Heisenberg’s principle of indeterminacy may *not* be one of them.<sup>2</sup>

In part of footnote 2, London (p. 162) quoted Russell (1943, p. 249) who noted Max Born’s preference for the concept of a “principle of limited measurability” over the concept of the uncertainty principle. Max Born was a Nobel Laureate in quantum physics.

Here, the “principle of limited measurability” is also deemed more useful, although its roots in the uncertainty/indeterminacy principle remain relevant. Applying Heisenberg’s principle to behavioral science, one cannot know completely how the acts of observing and measuring influence the behavior or physiology of the human or nonhuman animals who are being observed and measured. Particularly applicable to animal cognition and behavior is the “Rosenthal effect.”

## The Rosenthal Effect

Based on previous research conducted by Rosenthal and colleagues, Rosenthal (1963) provided a general account in *American Scientist* of what came to be known as the *Rosenthal effect*. The following quotation summarizes the essence of the *Rosenthal effect*:

For many of the sciences there seems to be little danger that the act of observation itself may change the object of study. . . . [Rosenthal did not cite and may have been unaware of Heisenberg (2007).] For the behavioral sciences, however, where humans or animals may be the object of study, the act of observation may very well change the object of study. (Rosenthal 1963, p. 268)

Further, Rosenthal and colleagues had shown that *observer expectations* may affect the behavior of the observed; it is this aspect of observer effects that most think of when they refer to the *Rosenthal effect*.

**The Rosenthal effect in animal cognition research.** The classic example of the *Rosenthal effect* in animal cognition research is that of Clever Hans. Interestingly, Rosenthal wrote the Introduction to the 1965 republication of the classic, *Clever Hans (The Horse of Mr. von Osten)* by Oskar Pfungst (1911); Pfungst was an early German psychologist. Rosenthal’s Introduction

should be required reading for anyone who studies animal cognition and, especially, those who work in the presence of the animals being studied. It will be instructive to recall some of the more relevant details about Clever Hans. All information here about Clever Hans comes from Rosenthal's Introduction, except for the comment below about marginal cue detection.

Clever Hans was best known for foot tapping (see below) the answer required in response to "questions" usually in the form of visual cues (see photo of Clever Hans and Mr. von Osten, (Fig. 2)). Presumably, Hans could add, subtract, read, spell, and identify musical tones as long as the question could be answered with foot tapping. Mr. von Osten sincerely believed that Hans's performances were genuine, and he invited critics to observe as Hans performed.

According to Rosenthal in Pfungst (1965, p. x):

...on September 4, 1904, thirteen men risked their professional reputations by certifying that Hans was receiving no intentional cues from his owner of any other questioner...these men, included in their number, a psychologist, a physiologist, a veterinarian, the Director of the Berlin Zoo, and a circus manager...

To jump ahead in the Clever Hans story, psychologist Oskar Pfungst conducted extensive studies that failed to reveal the basis of Hans's performance. Only when he put a visual barrier between Mr. von Osten and Hans did Hans's performances fail. Mr. von Osten was emitting inadvertent cues

that informed Hans when to begin tapping his foot and when to stop tapping. Cues might be such as a slight forward lean of the head or body or other inadvertent slight movements, cues that were undetected by the 13 motivated human observers. There was never any basis to believe that Mr. von Osten was aware that he was cueing Hans. Furthermore, Pfungst found that 23 of 25 questioners in the place of Mr. von Osten also engaged in inadvertent cueing of which they were unaware.

Somewhat lost in this story is the amazing ability of Hans to detect such marginal cues that went undetected by human observers who were deliberately looking for them. Whether other horses or other animals possess such marginal cue detection skill is a question worthy of further investigation.

Given that the questioners were unaware that they were emitting inadvertent cues, one should question whether this applies to contemporary investigators whose research occurs in the presence of their animal subjects. Perhaps all who study animal cognition today are aware of the lessons of Clever Hans, but it is doubtful whether any investigator who works in the presence of the animals can avoid inadvertent cues. Beran (2012) provided a commendable commentary intended to remind contemporary researchers in animal cognition of the hazards of inadvertent cues.

**An effort to avoid Clever Hans cues in animal research.** Harry Harlow invented the Wisconsin General Testing Apparatus (WGTA; see

## Reductionism,

**Fig. 2** Clever Hans and Mr. von Osten

separate entry about the “► [Wisconsin General Test Apparatus](#)” in this encyclopedia) as a way to avoid Clever Hans cues. The WGTA is essentially an enclosed box, illuminated inside, and with guillotine doors at the front and back. With the front door closed to prevent the animal seeing the experimenter set up a problem involving discriminanda and food reinforcers, the experimenter sits behind the WGTA and raises the back door to set up the problem. After setting up the problem, the experimenter closes her/his door and raises the front door so the animal can see the discriminanda and make its response. Correct responses typically are reinforced with a bit of food that is typically located in a food well beneath the discriminanda, and responses are observed by the experimenter usually through a one-way mirror and, historically at least, recorded by hand. With nonhuman primates who are micro-nosmic, it seems unlikely they would smell the food and make their responses on that basis, but with macronosmic animals, such as rats, it is best to have food beneath all discriminanda while also

using some means to prevent access to the food beneath incorrect discriminanda (see Bailey and Thomas 1998; Thomas and Noble 1988).

Often the WGTAs will have a tray or cart on wheels on which discriminanda are presented that can be pushed toward the animal in order to place the tray with the discriminanda within reach of the animal. Consider the apparatus below (from Thomas 1993) where the cart was designed with three guillotine doors (Fig. 3).

For example, as the cart moved forward toward the subject, strings and pulleys might raise all three doors as shown here; there were other possibilities (see Thomas 1993 for further details). In the trial shown here, when a heptagon appeared in the center door, the “difference” pair of objects was correct, and the subject needed to move the difference-object nearest the center door to reveal the food well and its food reinforcer. Had a triangle appeared in the center door, the correct response was to the sameness pair of trial-unique discriminanda.

The main point is that Thomas was concerned that one might hesitate in pushing the cart forward if

**Reductionism, Fig. 3** Apparatus and representative discriminanda. Here a heptagon in the center door is the cue to choose the member of the difference-pair of objects nearest the center door where a food reinforcer is in the exposed food well. Had the center door revealed a triangle,

the triangle would be the cue to choose the member of the sameness-pair nearest the center door. Unique, sameness-difference pairs of objects were used on each trial, and their left-right positions were determined quasi-randomly. Other options were tested; see Thomas (1993)

the animal appeared to be moving toward the incorrect choice. This suggests that even the WGTA can be fallible to experimenter bias, and other examples, even inadvertent and unrecognized, might be cited to show how experimenter bias might occur using the WGTA. All that Thomas could do was to encourage his examiners to be consistent in how they advanced the cart on each trial.

## Reductionism and Explanation

Reductionism does not mean that a person cannot be a good scientist and also limit her/his research to a given level. For example, B. F. Skinner forcefully and effectively advocated throughout his career that behavioral science can be done meaningfully and well without reduction to, say, physiology, as long as it fulfills two of the defining goals of science, namely, prediction and control.

Most behavioral scientists conduct their research with little concern about what happens inside the organism. They are interested only in controlling the stimuli presented to the organism and measuring its responses with the goal of achieving the greatest degree of prediction and control that their research enables them to achieve.

A brief digression may be useful to distinguish between “stimuli” and “discriminanda.” Those who use “discriminanda,” such as objects or

two-dimensional pictures or other representations, prefer “discriminanda” because a discriminandum may have several properties or features, and one may not always know to which feature a subject is responding. However, when one reduces the discriminanda to specific properties, such as, a 2,000 Hz versus a 5,000 Hz tone of equal loudness and duration, then it is appropriate to use the term “stimuli.”

The reductionist approach may be represented with a diagram such as Fig. 4. In Fig. 4, the focus is on the brain, but it is realized that other parts of the body are involved in behavior.

## Skinner’s View of Explanation Compared to a Reductionist’s Explanation

In Thomas’s commentary on Skinner’s article “Behaviorism at Fifty” (1963), Thomas (1988) quoted Skinner as follows:

An explanation is the demonstration of a functional relationship between behavior [responses] and manipulable or controllable variables [stimuli]. [Paragraph break] A different kind of explanation will arise when a physiology of behavior becomes available. It will fill the gaps between terminal events. ... It must be arrived at by independent observations and not by inference, or not by mentalistic constructions. (Thomas 1988, p. 650. Thomas’s commentary and Skinner’s response

**Reductionism, Fig. 4** Box representing and organism’s brain. Not shown here, but responses at one moment in time likely become part of the discriminanda in the next moment in time. Therefore, (a) the bases for inferences from observing discriminanda and responses as indicated

in the diagram are always changing, and (b) the exact meaning of behavioral concepts based on observations as indicated in the diagram also change, perhaps undetectably, from moment to moment

were reprinted in Catania & Harnad, 1988, with different page numbers, viz., 367–369)

Writing as a reductionist, the best explanation is equivalent to the best description together with conclusions related to prediction and control, and the more complete the description (e.g., via reductionism from behavior to physiology to neurochemistry, etc.), the better the explanation. The reductionist approach represented in Fig. 4 accomplishes the most complete description; therefore, the reductionist approach provides the best explanations. This author agrees with Skinner that, “It [explanation] must be arrived at by independent observations and not by inference, or not by mentalistic constructions.”

## Closing Remarks

Finally, Fig. 4, especially its Figure Legend, takes us back to earlier discussion here regarding limits on measurability as well as the involvement of uncertainty/indeterminacy. As indicated in the diagram and its legend, the neuronal morphology and the neurochemistry of the brain are continuously changing; therefore, what one observes, measures, and interprets at the behavioral level at one moment will change from moment to moment, even if unnoticeable or undetectable.

Such continuous changes in the organism and its behavior, together with the Rosenthal and Clever Hans effects, may appear to create a pessimistic perception of the future of behavioral science. However, all sciences are afflicted with uncertainties in observation and measurement, but most, including behavioral science, find sufficient constancy to obtain useful knowledge. This writer has sufficient confidence in the rabies vaccine that if he were to be bitten by a rabid animal, he would rely on the extremely high probability of the effectiveness of the rabies vaccine. This author is impressed by the high probabilities among the various sciences including behavioral science that enabled a human to walk on the moon, to place the Hubble telescope in outer space and enable it to send back observations and measurements that Galileo could only have dreamed, and to place to date (April 2019) the four rovers

*Sojourner, Opportunity, Spirit, and Curiosity* on Mars and design them to send back a wealth of information about Mars as well as to position themselves for optimal recharging of their batteries by the sun.

## Reference Memory

Bill Roberts

Western University, London, Ontario, Canada

The term *reference memory* was originally introduced by Werner K. Honig (1978). He defined reference memory as long-term memory for associations between two or more stimuli or between responses and the stimuli that follow them. Reference memories were often formed by repeated trials using the same stimuli and ending in reinforcement. Thus, memory for a path through a maze or for a conditioned habit, behaviors long studied by comparative psychologists, were forms of reference memory. Reference memory was distinguished from *working memory*, memory for events that occurred once on a single trial and had to be remembered only for the duration of the trial.

In a highly cited article, Olton and Papas (1979) showed that both reference and working memory could be studied on the radial maze. Using a 17-arm maze, eight of the arms contained food on every trial, but the remaining nine arms were always empty. The rat's task was to enter all the baited arms and avoid entering the empty arms. Avoiding the empty arms required reference memory because the same arms were empty on every trial. Visits to the baited arms, however, required working memory. Once a rat visited a baited arm and consumed its reward, the rat had to remember for the duration of the trial that it had already visited that arm. Thus, revisits to working

memory arms were working memory errors, and visits to reference memory arms were reference memory errors. Olton and Papas found that fimbria-fornix lesions to the rat's hippocampus impaired working memory but had no effect on reference memory. This study sparked a number of subsequent experiments that examined the role of brain structures and pharmacological manipulations in reference and working memory on the radial maze.

The interaction of reference and working memory has also been examined in another popular procedure used to study memory in pigeons, delayed matching-to-sample. On each trial of a session, a pigeon is initially presented with a red or green sample stimulus on the center key of a three-key panel. The sample then disappears and after a few seconds, red and green stimuli appear on the side keys. Choice of the side key that matches the sample yields reinforcement, but choice of the nonmatching side key does not. Working memory for the sample is high at 90% or better accuracy immediately after seeing the sample but declines as the retention interval increases. Roberts, Strang, and Macpherson examined pigeons' performance in this delayed matching task after pigeons had learned a reference memory. Pigeons were initially given visual discrimination training in which they saw red and green side keys on each trial but were only reinforced for choosing the red key. After pigeons learned to always choose the red key (reference memory), they were tested on delayed matching with red and green sample stimuli. When working and reference memory were congruent (red sample stimulus), matching accuracy remained high over a 10-s retention interval. When working and reference memory were incongruent (green sample stimulus), the retention curve dropped rapidly from 90% matching on an immediate test to chance (50% matching) at a 10-s retention interval. This pattern of performance with the green sample was quite important because it showed that working memory initially controlled choice behavior. As working memory faded, however, reference memory emerged as the dominant memory system controlling choice behavior. A human analog of this effect is remembering a friend's new

phone number immediately after hearing it (working memory) but later calling the friend's old phone number (reference memory). Roberts et al. (2015) further showed that this interaction of memory systems can be strengthened or weakened by manipulations that vary the strength of reference or working memory.

Reference memory may also be distinguished from a more recently discovered form of long-term memory called *episodic memory*. Although reference memories are well-learned habits based on repeated reinforcement, episodic memory is the memory for specific past events experienced by an individual animal. Experiments with scrub jays (Clayton and Dickinson 1998), rats (Babb and Crystal 2005), and other species now indicate that animals remember the details of specific prior experiences. Specifically, they remember what event occurred, where it occurred, and when in time it occurred. As memory research in animals has proceeded, we have learned that the reference memory habits studied for many years are only one of several memory systems and that reference memory may influence and be influenced by these other memory systems.

## Referential Communication

Marta B. Manser

Department of Evolutionary Biology and Environmental Studies, University of Zurich, Zurich, Switzerland

## Synonyms

[Arguments](#); [Conflicts](#); [Discussions](#)

Referential communication is defined as the interaction between signaler and receiver using referential signals that denote information about objects or events in the external environment. In humans, this typically corresponds to a mental representation in both parties and has been highlighted as an important element in the evolution of human language (Fitch 2010). In nonhuman animals (thereafter referred to as animals), the term of referential communication is used in a different way, as evidence for the relevant psychological states of mental representations is lacking, though the behavioral outcome appears to be comparable (Marler et al. 1992). To emphasize that while animal signals may function referential, but do not underlie the cognitive processes as in human communication, these signals have been called functionally referential (Macedonia and Evans 1993).

The prevailing text book example for functionally referential signals in animals are the different alarm call types used by vervet monkeys (*Chlorocebus aethiops*) that were described to show a distinct relationship to the appearance of specific types of predator types (Struhsaker 1967). Vervet monkeys produce structurally different alarm call types to terrestrial predators such as

leopards than to eagles in the air or snakes. Playbacks in the natural habitat of the monkeys were used to demonstrate that these different alarm call types elicit different predator-specific escape responses as if the real predator was approaching (Seyfarth et al. 1980a, b). The playback of a terrestrial alarm call results in receivers running into the tree, while an aerial alarm call drives them either into the next bush or the center of the tree if already sitting up, and the snake alarm call induces them to stand up bipedally and monitor the ground next to them. These findings of the production of predator-specific alarm calls have been confirmed in several other species, including nonprimate mammal and bird species (for recent reviews on mammals, see Townsend and Manser 2013, on birds Gill and Bierema 2013; Smith 2017). These studies all indicate that the structural variation between these alarm call types seem meaningful, as they are emitted in highly specific contexts to a certain predator type and enable the receivers to show the appropriate predator-specific escape response.

Highly context-specific signaling referring to external events have also been described in the context of animals encountering food (Clay et al. 2012). The first functionally referential signal described is the honeybee waggle dance (von Frisch 1974), which refers to the direction and in some species also the distance to the foraging patch. Chimpanzees (*Pan troglodytes*) (Slocombe and Zuberbühler 2006) and bonobos (*Pan paniscus*), as well as rhesus macaques (*Macaca mulatta*) (Hauser and Marler 1993), capuchin monkeys (*Cebus capucinus*) (Gros-Louis 2002) produce calls when finding food that are acoustically distinct depending on food quality or desirability. The description of the specific context showed that the likelihood to produce one food call type and not another in apes also varied between groups (Clay et al. 2012), and in capuchin monkeys, it depends very much on which individuals are close by as potential receivers (Gros-Louis 2002). Food calls are also described for ravens (*Corvus corax*), where they increased in their number of “haa” calls depending on their food preferences (Bugnyar et al. 2001). However, whether the receivers relate the variation in vocalizations to

the signaler’s perceived food quality has not been experimentally shown, although based on natural observations, these calls recruit other ravens to the location of the calling individual (Heinrich and Marzluff 1991).

## Defining Functional Referentiality

The model put forward by Macedonia and Evans (1993) defining functionally referential communication requires a high production specificity and a high perception specificity of the different alarm call types within a species. Call types can only be regarded as functionally referential, if two specific conditions are met: the call type must be produced in close association to a specific external event or object and the receivers must respond to the call type as if the stimuli was present. However, this does not imply what aspect of the external stimuli is responsible to induce the specific call type. For example, studies on referential alarm calls suggest that in some species, call types are associated with specific predator species (Gunnison’s prairie dogs (*Cynomys gunnisoni*) Slobodchikoff and Placer 2006), while in others they seem to refer to behavior of the predator (Siberian jay (Griesser 2008), and in most cases, it is not clear whether it is the spatial location (air versus ground) or aerial versus terrestrial approach (fast versus slow) the call refers to (e.g., meerkats, *Suricata suricatta*) (Manser 2001).

Recent studies provide evidence for the combination of meaningful, highly specific call types put into a sequence, whereby the combinations of the calls carry the meaning of the single call types. Thereby different types of sequences have been described depending on the combination of the two call types (recent review Collier et al. 2014). A first type is the use of an affixation system by Campbell monkeys (*Cercopithecus campbelli campbelli*) (Ouattara et al. 2009). They add an affix to both of their predator-type specific calls to produce new calls with a different meaning. The terrestrial alarm call with the additional suffix is given to any disturbance, while the aerial alarm call with the affix is given to any disturbance in the canopy. It seems the addition of the affix modifies the meaning of the predator type specific

calls into a less specific disturbance call in the according physical space indicated by the specificity of the predator type. The second type of meaningful sequences is the use of two predator-type specific calls, terrestrial and aerial calls, in combination, as described for putty-nosed monkeys (*Cercopithecus nictitans*) (Arnold and Zuberbühler 2006). The combination of the calls elicit movement of the calls, rather than the predator-type specific response given to each of the call types themselves. Different to the Campbell monkey combinations, here the meaning of the sequence seems not to derive from the meaning of the components. Recent studies on call sequences in animals have described the combinations of two meaningful call types; however, these are typically not based on functionally referential calls that seem to refer to an external event or object. Many call combinations have been described in the context of mobbing predators to recruit other group members to the caller (Suzuki et al. 2016), or in social context where calls are related to the behavior or the general context the caller experiences (Collier et al. 2014).

### The Level of Specificity on the Production and Perception Side

A recurrent pattern described is that typically the alarm calls to aerial predators are more specific to a narrow range of predators, and therefore more functionally referential, than alarm calls to terrestrial predators. For example, in lemurs (*Eulemur fulvus*), a distinct aerial call type refers specifically to hawks while terrestrial alarm calls given in response to fossa, dog, and baboon calls are also given to other disturbances (Fitchel and Kappeler 2002). A similar pattern is found in blue monkeys (*Cercopithecus mitis*) who emit pyows to an even broader array of stimuli including dog, snakes, motorcycle, civet, and baboons (Fuller 2014). There are at least three possible explanations for this recurring pattern. First, aerial alarm calls are typically of high urgency and require immediate responses. Receivers cannot afford the time to attend to any contextual information before responding. In contrast, terrestrial predators

typically approach at slower speeds which gives receivers more opportunities to gather additional contextual information and then respond. Second, animals may categorize the threat differently than us humans, and therefore we perceive the stimuli they respond to on a variation of terrestrial stimuli as broad, versus raptors to approach as a very clear defined narrow category. None of the studies so far published on functionally referential calls has thoroughly addressed this question, as it is a huge effort to determine how a species categorizes its environment (Townsend and Manser 2013; Zuberbühler and Neuman 2017).

We also find variation in the perception specificity of the receiver's response to the functional referential signals. Recent studies on different vervet monkey populations have shown that the response of receivers to the originally described functionally referential call types elicit qualitatively different responses for the same predator type call. Ducheminsky et al. (2014) showed in response to playbacks of alarm calls that receivers often looked first towards the speaker and either did not show escape behavior or delayed. This variation in receiver response across populations could indicate a lack of perception specificity, or it may reflect the fact that we find variation in the recipients depending on their own situation. If they are close to shelter, they may not have to run immediately but can take additional cues into account for their appropriate response. Diana monkeys respond to guinea fowl alarm calls with leopard alarm calls themselves, as if a leopard were present, but they remain silent when they seem to have a situation indicating that the guinea fowls calls were given to chimpanzee or humans, potentially hunting for the monkeys (Zuberbühler 2000). This has also been demonstrated in dwarf mongoose, where receivers take their own situation into account whether to respond and how fast and intense (Kern et al. 2017).

### Limitations of the Theoretical Framework

This variation in production and perception has recently brought up some criticism on the concept

of functional referentiality and its current definition (Wheeler and Fischer 2012). The basic argument is that any call type, whether highly context specific to the external environment of the signaler or referring to the signaler's behavioral state, conveys some referential information to the receiver. From this argument, the observed signals should be seen along a continuum rather than be divided into discrete categories, functionally referential versus other call types, in the past usually referred to as motivational signals expressing the behavioral context of the caller. Yet, the theoretical framework has hold up and seems to be helpful in stimulating new research (Scarantino and Clay 2015). Also, besides the specific information to the external event, it is likely any vocalization shows some variation relating to traits of the caller, such as indexical information or the intrinsic (motivational) state of the caller (Manser et al. 2002). One could then argue we should go along a multidimensional characterization of the signal structure, where referentiality could be identified for each of these different types of traits. For example, the individual signature conveying unique information on the identity of the caller, the expression of the motivational state reflecting the behavior of the caller, etc... (Manser 2016). The obvious difference here is that it is not referring to a stimuli in the external environment of the caller.

### **Selective Pressures on Evolving Functionally Referential Signals**

The evolution of referential signals in animals seems to vary depending on the context, whereby in all cases the need to provide accurate information on the external stimuli to enable the receiver to make the appropriate decision how to respond seems the driving factor. This is very obvious in the situation of the alarm call types in vervet monkeys and some other species, where different escape responses to the different predator types in a three-dimensional space are of benefit (Macedonia and Evans 1993). However, e.g., in meerkats, this seems not the full explanation, as the ground squirrel living in the same habitat do not use predator type specific

calls. Rather, the argument has been that social aspects to keep cohesion with the group may explain the need for functional referential calls (Furrer and Manser 2009). Even less clear are the selective pressures underlying food calls (Clay et al. 2012). While in alarm calls, the urgency aspect which does not allow to monitor for additional contextual cue due to time constraints seems logical, this does not apply on food calls. Here, rather social reasons, in particular the social structure of the group has been put forward as explanation, where finding high quality food and share it with group members may be linked to social rank and enhance the establishment of the reputation of the caller.

### **Nonvocal Functionally Referential Signals**

Referential signals in animals other than vocalizations include visual signals, such as the bee dance or gestures described for primates, birds, and potentially also fish (Smith 2017). Most research has been done on the acoustic modality, likely due to the difficulties in identifying and manipulating visual signals, and convincingly test whether the criteria for production and perception specificity apply. In the gesture studies in primates, the production of single gestures and also combinations of them is highly specific to an external stimuli (Hobaiter and Byrne 2014). In birds, they point with their body and head towards the predator and the other group members apply the same pointing position. This behavior has been suggested to meet the criteria for referential gestures, as the signal is directed towards the eliciting referent and seems ineffective for other purposes (Pika and Bugynar 2011). Whether the body vibration signal of the fish to recruit an eel to join the cooperative hunt (Vail et al. 2013) also fits the criteria of a functional referential signal is something to discuss (Smith 2017). Similar to the vocal recruitment calls in the bird studies, it may just represent the social recruitment for hunting together from the signaler side, while for the receiver it may refer to prey. These would then only be object specific on the receiver side but not on the production side (Seyfarth and Cheney 2003).

## Functionally Referential Signals and the Evolution of Human Language

An obvious approach, when trying to understand the evolution of human language, is the comparison to animal communication, and in particular identify and compare the underlying cognitive mechanisms. Zuberbühler and Neuman (2017) suggest that in humans at least three levels of information processes for the referential nature of human language need to be considered: (a) fulfill the criteria of functional referentiality with the production of distinct signals to specific external events or objects; (b) the signaler taking the nature and the composition of the audience into account; and (c) the ability of the signaler to take the knowledge of the audience into account. Over the last decades, empirical evidence in several animal species for the first aspect on the production of functionally referential signals has been convincingly accumulated, and in several circumstances, the signalers also seem to be aware of the nature of the audience and adjust their signaling accordingly. In contrast, only for chimpanzees, empirical evidence exists that animals are also able to take into account the knowledge state of the receiver (Crockford et al. 2012), while in human communication, all of the three cognitive processes seem to be present, often at the same time.

## Conclusions

The study of referential signals in animals still seems to be a useful theoretical framework for the understanding of the evolution of animal communication and human language. It has stimulated much research in identifying the underlying cognitive mechanisms involved in animal communication. The critical evaluation of the theoretical framework of referentiality in animals has helped to rethink and potentially in the future also to extend it in aspects that may advance the understanding of information processes involved in communication. The application of linguistic concepts can help to formulate new hypotheses but also needs to be applied with caution and any

conclusion need an objective evaluation of the existing empirical evidence in animal communication. To produce such evidence is challenging, as the according experiments in animals are difficult, in particular also to perform the correct control situations. We are still far away in understanding how animals categorize their environment, and therefore it is difficult to make unbiased interpretations of what information affects the signaler in the production of signals, and what information is of importance in the response of the receivers.

## Introduction

The upper part of the digestive system serves as the conduit for the passage of food from the area of ingestion to the stomach. There are two sphincters, in the upper and lower part of the esophagus, that regulate the entry of gastric contents. The opening of the lower esophageal sphincter (LES) is mediated by the vagal impulses. The sphincter, in routine conditions, is taut enough to prevent the reflux of digested contents into the esophagus. The absence of tautness leads to esophagitis, resulting in the “heartburn” sensation. In contrast to humans, in whom abnormal regurgitation leads

to disturbing symptoms, ruminants regularly present with the discharge of food into the esophagus (Dirksen 2002). In many cases, regurgitation is misdiagnosed as vomiting. But it should be taken into account that vomiting will always present with a period of restlessness and forceful exit of food from mouth or nose. Regurgitation is defined as the reflux of gastric contents into the esophagus for a defined period of 30 s or longer and associated with a decrease in esophageal pH to <4 (reflux of gastric acid). In many cases, regurgitation is misdiagnosed as vomiting. But it should be taken into account that vomiting will always present with a period of restlessness and forceful exit of food from mouth or nose.

## Mechanism for Regurgitation

There are several plausible mechanisms for regurgitation. First, regurgitated contents enter the esophagus because of phasic elevations in pressure developing as a result of contractions in the rumen (Colin 1871). This is found to increase with inspiration, which suggests that diaphragmatic contractions have a small role to play. Second, regurgitation may manifest as a result of decrease in intrathoracic pressure during inspiration against a closed glottis. This happens usually just before the forward passage of a food bolus (Touissant 1875). Finally, it may be that alternate shortening and contraction of longitudinal and circular muscles results in the fall of intraesophageal pressure. Subsequently, the esophagus becomes a cone-shaped infundibulum projecting to the cardia and the aspiration of contents (Wester 1926).

Carr et al. (1983) performed manometer-based recordings of the esophagus in sheep and observed variable patterns of contractile activity during eructation, regurgitation, and peristalsis. Eructation had small spurts of passive increase in pressure of 7–15 mmHg which caused the entry of gas into the esophagus. During regurgitation, contractions moved cranially and compared to the contractions observed during eructation, those observed during regurgitation were more intense and regular. While contractions of eructation terminated in the caudal part of the thoracic esophagus, regurgitation could be

documented in all parts of the esophagus. The differential pattern of contraction during eructation, regurgitation, and peristalsis could be attributed to the variations in the stimuli producing these. Thus, it could be hypothesized that regurgitation can be differentiated from other types of movements because the food contents travel in reverse direction in contrast to others.

The proportion of esophagus disposed in the abdominal cavity is one of the crucial factors in determining the chances of regurgitation in a particular species. In species where the esophagus is completely within the thoracic cavity, the chances of gastroesophageal reflux are comparatively higher (Pratschke et al. 2001). This can be attributed to the fact that the portion of esophagus in the abdominal cavity, by virtue of its shorter radius, develops greater pressure in accordance with Laplace law. Differential pressure generated over gastroesophageal junction helps in preventing the regurgitation (Pratschke et al. 2001). In support of this hypothesis, rats having two distinct elevated pressure regions in the upper gastrointestinal system along with a distinct abdominal part of esophagus lack the ability to vomit and seldom have chances of developing reflux (Soto et al. 1997). Thus, it can be postulated that distension of esophagus when food contents propel in a retrograde direction and in the absence of swallowing could initiate minimal propulsive esophageal contractions as well as relaxation of LES. These peristaltic contractions primarily serve to clear the esophagus of its refluxed contents and are referred as secondary peristalsis. These do not involve the conventional pathway encompassing the medullary swallowing center and are mostly mediated by localized nervous plexuses within the muscles comprising of non-adrenergic and non-cholinergic (NANC) nerve endings. Inhibition of NANC nerve endings causes sphincter relaxation. This can be observed when drugs such as ketamine and midazolam are administered for anaesthetizing dogs during surgical procedures (Kohjitani et al. 2005). It is interesting to note that the regurgitation phase of rumination in adult herbivorous animals shares the mechanism of vomiting (Watson 1941). Similarly, the resoesophageal groove reflex takes place in young

ruminants which helps them to bypass the primitive rumen. Thus, it is difficult to differentiate the regurgitation phase of rumination and vomiting which could plausibly be due to the shared neural coordination pathways for both acts.

Titchen (1979) observed the esophageal and diaphragmatic activity during regurgitation using electromyography and found the contraction of the lower esophagus developed about 2 s before the regurgitation act. Regurgitation was associated with inspiration which ceased the esophageal contraction. The inspiration was due to the contraction of the costal fibers of the diaphragm. The same hypothesis could be extended to understand why heavier dogs have higher risk of regurgitation. These dogs often have distorted proportion of thoracic cavities which could influence gastric pressure and the contractile activity of their diaphragms (Anand and Katz 2010). Yet another closely related condition with regurgitation is mega-esophagus which might either be congenital or acquired (Smith 2009). Here, the dilated part of esophagus is dysfunctional and gets filled with ingested contents, resulting in regurgitation (Smith 2009). Szczesniak et al. (2011) conducted a landmark study to decode esophagus-pharyngeal regurgitation in humans and found that a few salient features underlie the condition. First, most of the regurgitation episodes took place when subjects were upright. Second, a certain degree of upper esophageal relaxation preceded the regurgitation episodes, and these brief episodes of non-swallow-related relaxation could be considered as the pathognomonic mechanism of regurgitation. Finally, unless the relaxation happened, even significant amount of abdominal strain could not precipitate regurgitation.

## Regurgitation and Veterinary Practice

Regurgitation constitutes a significant issue during the surgical procedures in veterinary medical practice especially while administering anesthetic medication which would potentially relax the lower esophageal sphincter (Vlasin et al. 2004). In such situations, external compression offered

by diaphragmatic fibers fails in addition to the internal factor constituted by lower esophageal musculature. Acepromazine in particular is one of the pre-anesthetic medications that is associated with a 29% increased risk of gastroesophageal reflux because of the reduction in lower esophageal sphincter pressure (Wilson et al. 2005). However, these effects haven't been significantly documented in studies involving larger sample sizes and therefore the risk of developing reflux alone need not be taken as a stand-alone determinant while choosing the anesthetic agent.

To conclude, regurgitation is a normal phenomenon in ruminants and this might be coordinated by pathways in the medullary region, similar the pathways used to stimulate vomiting. However, there are also abnormal causes of regurgitation, stemming from anatomical obstruction in the esophagus. In such cases, a detailed examination along with possible diagnostics might help in planning the required management protocol.

## Rehearsal

Benjamin M. Basile

Section on the Neurobiology of Learning and Memory, Laboratory of Neuropsychology, National Institute of Mental Health, NIH, Bethesda, MD, USA  
Yerkes National Primate Research Center and Department of Psychology, Emory University, Atlanta, GA, USA

## Synonyms

Central executive; Cognitive control; Working memory

Rehearsal is the effortful maintenance of information in working memory. For example, you

rehearse when you mentally repeat to yourself the name of somebody you just met, or the six items your spouse asked you to pick up at the market. Rehearsal, along with mental manipulation, is a characteristic process of working memory. Active working memory is most often contrasted with passive short-term memory, in which information continues to be available over short delays, but is not effortfully maintained.

In humans, rehearsal is most often studied using verbal or verbalizable stimuli and then takes the form of vocal or subvocal repetition. This vocal repetition is often called a “phonological loop” (Baddeley et al. 1998). Some of the many findings from research into human rehearsal are: Rehearsal allows the maintenance of information across an extended time, when otherwise that information would be rapidly lost. Rehearsal is cognitively effortful, in that cognitive distraction interrupts rehearsal and results in the loss of information from memory. Rehearsal is limited to a capacity of four to seven unrelated items. Rehearsal is domain dependent, in that distractors from the same domain will interfere with rehearsal more than distractors from another domain (e.g., rehearsal of numbers is more impaired by a numerical distraction task than an image distraction task).

In nonhuman animals, evidence for rehearsal is surprisingly mixed. First, it is difficult to infer rehearsal from nonhuman studies of working memory because the comparative literature has historically used the term working memory differently than in the human literature. In the human literature, working memory necessarily includes some type of effortful maintenance, such as rehearsal. In the comparative literature, working memory often refers to the operational definition of whatever memory the subject needs to remember for the current trial or session, such as a rat knowing which locations in a radial maze have already been searched today. This definition of working memory is contrasted with reference memory, which is the information the animal needs to apply to all sessions, such as a rat knowing the rule that food is sometimes hidden at the end of radial maze arms. Notably, the historical comparative definition does not specify any

psychological properties of working memory other than that it is used in the current session, meaning that many reports of working memory in nonhuman animals can be attributed to memory systems that do not rely on effortful rehearsal.

Outside of the comparative psychology literature, neuroscientific studies have a long history of attempting to measure the neural bases of rehearsal in nonhuman animals, usually monkeys, remembering items over short periods of time. In most of these studies, monkeys must remember an image or a spatial location over a short retention interval, sometimes while ignoring other images. Researchers then record electrical activity from different brain areas, such as the prefrontal cortex. The assumption of many of these studies is that monkeys are rehearsing. Consistent with this, researchers have found neurons in the brains of both monkeys and corvids that show persistent elevated activity over the retention interval, which has been interpreted as the neural signature of the animal effortfully keeping this information in working memory via rehearsal (Goldman-Rakic 1995; Hartmann et al. 2017). However, later behavioral investigations with monkeys revealed that humans and monkeys solved these tasks in different ways (Wittig et al. 2016). Humans overwhelmingly differentiated between to-be-remembered images from the current trial and those from previous trials, suggesting targeted rehearsal of specific items. Whereas monkeys indiscriminately remembered items from all trials, suggesting that monkeys were primarily judging items based on a decaying passive familiarity trace rather than using targeted rehearsal. Thus, persistent neural firing per se is not necessarily evidence of working memory and is difficult to interpret without behavioral validation.

A surprising number of behavioral studies have concluded that nonhuman animals either do not actively rehearse, or only rehearse under limited circumstances. Humans’ performance increases when they have more time to rehearse between items in a to-be-remembered list, but monkeys’ performance does not (Cook et al. 1991). Humans’ memory accuracy is decreased by a distractor task such that more involved distractor tasks decrease accuracy more, but

monkeys' accuracy is decreased by a set amount regardless of how involved the distractor task is (Washburn and Astur 1998). In pigeons, many of the putative demonstrations of directed forgetting, in which targeted rehearsal is inferred due to an accuracy increase for items that subjects are instructed to remember, were later shown to be task artifacts due to reward availability or surprise (Zentall et al. 1995). Furthermore, studies of single-neuron activity in pigeons performing these directed forgetting tasks were originally interpreted as reflecting sustained rehearsal activity, as in similar monkey studies, but later studies showed that the persistent neural activity over the retention interval was related to reward availability rather than stimulus maintenance (Browning et al. 2011).

Some studies have provided good evidence for rehearsal in nonhuman animals, but even these suggest that it is probably not the predominant strategy and likely occurs only under limited circumstances. In directed forgetting paradigms, pigeons and monkeys showed evidence of rehearsal that was not subject to the previous criticisms, but the narrow task parameters necessary to prevent subjects from using alternative strategies perhaps speak to how readily these species use working memory when not required (Tu and Hampton 2014; Zentall et al. 1995). In dual-task paradigms that present a second task during the retention interval, monkeys' decrement in memory accuracy scaled to the difficulty of the distraction task, but only if the to-be-remembered items were from a small set of familiar images (Basile and Hampton 2013). Similarly, monkeys showed robust primacy, the increased memory for initial list items that is sometimes due to rehearsal in humans, with small sets of familiar items but not large sets of unfamiliar items (Basile and Hampton 2010). In a direct comparison with humans, evidence of rehearsal in monkeys was limited to task conditions with small sets of stimuli or frequent distractor images, whereas humans showed evidence of rehearsal across most tests, even those for which active rehearsal was likely unnecessary (Wittig et al. 2016). In all these cases, when the task parameters did not pressure monkeys to rely on rehearsal, monkeys seemed to use

a passively decaying familiarity trace. Taken together, these studies indicate that some non-human species can rehearse under some circumstances; however, rehearsal appears to be the dominant memory strategy only in humans.

In summary, rehearsal is the effortful maintenance of information in working memory. It is often contrasted to passive short-term memory. Comparatively, the most-noticeable species difference appears to be that humans, but not non-humans, are predisposed to rehearse even when unnecessary, which may point to the unique utility of language in rehearsal. Surprisingly, much evidence suggests that nonhuman animals rarely rehearse. Nonetheless, there is good evidence that nonhuman animals do rehearse, but likely only in limited circumstances.

## Relational Concepts and Symbolic Logic

Roger K. Thomas

Department of Psychology, University of Georgia, Athens, GA, USA

### Introduction

“Relational concepts” means different things to various investigators. Fortunately, any experimental task and procedure used by any animal research investigator can be reduced to the fundamental ways that Bourne (1970) and Thomas (1980) defined relational concepts. Bourne based all concepts on five basic logical operations and their complements, and he used tasks that were constructed consistently with the truth table that defined each of the five primary and complementary logical operations. Bourne referred to the five primary and complementary truth-table-based operations as “rules,” and that term will be used here as Bourne used it. In order from most basic to most complex and with the primary listed first and the complementary listed second here, the five basic pairs of rules are (a) affirmation and negation, (b) conjunctive and alternative denial, (c) inclusive disjunction and joint denial, (d) conditional and exclusion, and (e) biconditional and exclusive disjunctive.

Thomas (1980) drew heavily from Bourne (1970) and Gagné (1970), to construct a hierarchy of eight fundamental types of learning. Any and all learning tasks and procedures, no matter how complex, can be reduced to one of or combinations of the eight types in the hierarchy Thomas (1980) constructed; see Thomas (1996) and Bailey et al. (2007) for slight modifications to the 1980 hierarchy. The eight types and their levels in Thomas's hierarchy (1980) are (a) Level 1: Habituation and its opposite, Sensitization, (b) Level 2: Classical or Pavlovian Conditioning, (c) Level 3: S-R Learning also known as Operant Conditioning, (d) Level 4: Chaining of S-R units, (e) Level 5: Concurrent Discrimination Learning, (f) Level 6: Class Concepts, (g) Level 7: Relational Concepts I, and

(h) Level 8: Relational Concepts II. Following Gagné (1970), that the types of learning are hierarchical is based on lower levels being prerequisites for higher levels, although Thomas believes Levels 2 and 3 may be parallel levels.

Thomas (1980) mostly followed Gagné (1970) for the first five levels, but Gagné, an educational psychologist, focused his highest three levels on tasks (mostly verbal tasks) that were primarily used to study human learning and that were *mostly not usable* with animals. Thomas realized that he could base his highest three levels on Bourne's (1970) approach to concepts and that all of the tasks at Gagné's highest levels could be reduced to Bourne's three levels. Thus, Thomas identified Level 6: Class Concepts as based on Affirmation and Negation. Agreeing with Bourne that concepts based on Conjunctive, Disjunctive, and Conditional rules involved parallel operations, Thomas used them for Level 7: Relational Concepts I. Again, agreeing with Bourne, that Conditionals are prerequisites for Biconditionals, Thomas identified Level 8 as Relational Concepts II based on Biconditionals. *One or more Level 6: Class Concepts must be involved to construct tasks that assess Relational Concept use at Levels 7 and 8.* In most instances of problem-solving by an animal, whether in the laboratory or in its natural habitat, an animal might use several types of learning from Thomas's hierarchy serially and/or concurrently as the task solution requires.

## Class Concepts

To affirm a discriminandum as being an exemplar of a Class Concept, tasks must use trial-unique discriminanda, or if discriminanda are used more than once, evidence of concept learning must be limited to first-trial performances; otherwise, the animal might perform the tasks successfully by rote learning based on trial and error. Thomas (1980) distinguished between Absolute and Relative Class Concept use based on the operational difference that (a) to affirm a discriminandum as being an exemplar of an absolute class concept, the animal *need not compare discriminanda* but

(b) to affirm a discriminandum as being an exemplar of a relative class concept, the animal *must compare discriminanda*.

For example, if the concept of interest is "tree," and, among two or more discriminanda presented to the animal, one is obviously a tree and, if the animal *knows or learns* the concept (see quotation from Hayes and Nissen (1971, in the next paragraph) of "tree," *it need not compare other discriminanda* to affirm that each new exemplar of a tree is an example of the absolute class concept "tree." The most used example of a relative class concept in the animal learning/cognition literature has been the Oddity task. The most common method to study oddity is to present three discriminanda, two of which, the nonodd discriminanda, are identical, and the other discriminandum, the odd one, differs in color form and size from the nonodd discriminanda. To affirm the odd discriminandum, the animal *must compare* all discriminanda.

Before leaving this section, this is a good place to remind all who study use of class concepts by animals of what Hayes and Nissen's wrote in 1971.

We cannot imagine any set of operations, applied to any subject, that could detect a concept without at the same time operating to induce its formation. (Hayes and Nissen, 1971, p. 79)

After quoting Hayes and Nissen, Thomas and Ingram (1979, p. 42) added,

In other words, the acquisition of new concepts and the detection of existing concepts are hopelessly confounded with the subject's acquisition of the reinforcement contingencies, thus the distinction between newly learned and existing concept use is scientifically meaningless.

Most animal cognition investigators, including this writer, have tended to write about animals "learning" concepts when, as just shown, that cannot be known. However, that is not likely to be an easy habit to break. Hayes and Nissen's statement and Thomas and Ingram's addition *do not apply* to learning to use relational concepts. Relational concept learning requires using class concepts in relation to other discriminanda which may or may not be conceptual and then determining via experience (learning) over trials what that relationship is. One cannot imagine an animal

approaching such a task with a prior knowledge of the relationship being investigated. In other words, an animal cannot preemptively know that there is a relationship between, for example, “triangularity *and* sameness” or “*if* triangle, *then* sameness,” because the relationship contingency in a given test is determined arbitrarily by the experimenter, and it is the animal’s task to determine what it is.

**Uses of Some Relational Concepts Are So Far Unknown**

The complementary rules identified above and the biconditional apparently have never been investigated using nonhuman animals, so these six will not be considered further here. However, these are equally valid and may become relational concepts to be investigated by future animal researchers. Furthermore, it is doubtful whether any animal investigator using animals has determined whether disjunctive relational concepts that conform to the truth table has been determined conclusively; this will be discussed in the next section. Conjunctive and conditional concepts will be considered extensively in later sections.

**Disjunctive Relational Concepts**

Wells and Deffenbacher (1967) investigated the use of conjunctive and disjunctive concepts by squirrel monkeys, and there may be others unknown to this writer, but it is doubtful if any experiments have conformed to either of the two truth tables for the disjunctive (see below). Wells and Deffenbacher (1967) will be used to examine the issues. Wells and Deffenbacher used 81 discriminanda that varied in size (large, medium, small), shape (triangle, circle, square), color (green, yellow, blue), and patterns within a figure (cross, vertical stripes, cross-hatching). Apparently, these were two-dimensional figures pasted on “the face of” 2" × 2" wooden blocks. Their chosen attributes for the disjunctive were large-square and yellow-cross. There are two

types of Disjunctive; one is known as the Inclusive Disjunction (sometimes symbolized in a truth table as  $\vee$ ) and the other is known as the Exclusive Disjunctive (sometimes symbolized  $\neq$ ). Wells and Deffenbacher did not specify which they studied, but one can infer reasonably that they meant the Exclusive Disjunction, and that will be the one diagrammed below. Wells and Deffenbacher’s Exclusive Disjunction might be verbalized as “all patterns that are large-square or yellow-cross are correct exemplars.”

**Exclusive Disjunctive Truth Table Illustrated with Discriminanda**

| p                  | q                  | $p \neq q$  |
|--------------------|--------------------|-------------|
| T large square     | T yellow cross     | T correct   |
| T large square     | F not-yellow cross | T correct   |
| F not-large square | T yellow cross     | T correct   |
| F not large square | F not-yellow cross | F incorrect |

“ $\neq$ ” is the symbol for the exclusive disjunctive

Row 1 shows that any large-square discriminandum or any yellow-cross discriminandum when chosen by the monkeys is correct, while any other discriminanda are not. Row 2 shows that any large-square is correct, yellow-cross is not to be presented, and any other discriminandum there is incorrect. Row 3 shows that any yellow-cross is correct, red-square is not to be presented, and any other discriminandum is incorrect. It is not clear whether Wells and Deffenbacher’s procedures included trials that corresponded to row 4, namely to present discriminanda to the monkeys that are not a red-square or a yellow-cross to assess whether the monkeys made no choices on such trials. Assuming that was the case, their research regarding the Disjunctive is regarded here as inconclusive. Although it is unknown whether the truth table for the conjunctive was considered by Wells and Deffenbacher, their demonstration of monkeys’ use of a conjunctive rule might be valid. However, the way they reported the results leaves this writer unable to determine whether their squirrel monkeys might have learned the reinforcement contingencies for either or both the conjunctive or the disjunctive by rote.

## Misuse of the “Conditional Discrimination” Task

There is a long history of animals being tested on “conditional discrimination” problems and being misinterpreted as providing evidence of the use of a conditional rule. Paraphrasing French (1965), the basic conditional discrimination task involves a set of simultaneously presented discriminanda and a set of successively presented discriminanda; typically, two or more simultaneous discriminanda are used on each trial but only one successive discriminandum is used on each trial. Dozens or more experiments referred to as learning a conditional discrimination as French defined it have been used with animals and humans, but most successful performances can be attributed to rote learning based on trial and error.

An easy example might be to use a red block and a blue pyramid as the simultaneous discriminanda and white or black trays on which the simultaneous discriminanda are presented as the successive discriminanda. The experimenter determines the reinforcement contingencies and, for example, when the objects appear on the white tray, responses to the block might be correct, and when they are presented on the black tray, responses to the pyramid might be correct. There have been too many investigators to reference here (including this author earlier in his career) who interpreted the results of conditional discrimination testing as providing evidence for their subjects having used conditional rules such as “if the tray is white, then the red block is correct” or “if the tray is black, then the blue pyramid is correct” when the task was not constructed to meet the conditions of the truth table for use of a conditional rule and when the task might have been learned by rote.

Maier and Maier (1970) described conditional discrimination as a measure of concept learning. That might be correct in some cases (see two examples below), but most conditional discrimination tasks used with animals do not provide evidence of conceptual conditional discrimination; rather, they likely involved learning by rote. Interpreting such results as reflecting an animal’s use of a conditional rule is at best inconclusive and is most likely incorrect.

An early study using rhesus monkeys and a conditional discrimination task as French (1965) defined it was by Spaet and Harlow (1943). They did not use the term “conditional discrimination”; rather, they referred to their investigation as involving “multiple sign problems.” They administered two tasks. The simultaneous discriminanda in both tasks were the same three identical brass doorbell buttons (hereafter “button” for short) and same three identical T-shaped objects. The successive discriminanda were yellow or black trays on which the simultaneous discriminanda were presented. Spaet and Harlow’s (1943) first task involved oddity problems where a button or a T might be odd and two buttons or two Ts might be nonodd simultaneous discriminanda. If the oddity problem was presented on the yellow tray, the odd object, either the button or the T, was correct, and if the tray was black, either of the nonodd discriminanda, either of two buttons or two Ts, was correct. Food reinforcers were used for correct responses.

Spaet and Harlow were not clear whether the odd object might appear in the left (L), center (C), or right (R) positions versus only on the L or R right positions. If the L-C-R positions were used and, given that the same six simultaneous discriminanda were used, only six specific configurations of object presentations were possible. If only the L-R positions were used, only four specific configurations of object presentations were possible. With only four or six specific configurations, it is possible the monkeys learned the specific configurations by rote. For the second task, when three buttons appeared on the yellow tray, the correct choice was to the left-most button. When three Ts were presented on the yellow tray, the right-most T was correct. These contingencies were reversed on the black tray. With this task, only four specific configurations were possible. That the monkeys required from 4320 to 6840 trials to learn both tasks suggest that they learned the different configurations by rote. Nissen (1951) trained a chimpanzee on 16 concurrently presented conditional discrimination problems, and it took 15,796 trials to learn them. Nissen was unsure how the animal performed the task, but the following appear in his

discussion of how the chimpanzee, Frank, might have performed.

... it might be that each of the ... [discriminanda] ... was learned more or less independently (p. 14) [four paragraphs later]. It still remains possible, however, that Frank did become responsive to ... a principle but that its expression in overt behavior was obscured by prepotent effects on a "lower level." (p. 15)

Thomas and Kerr (1976) tested three squirrel monkeys on a task involving trial-unique oddity problems as the simultaneous discriminanda, and black or white trays on which to present the oddity problems as the successive discriminanda. Responses to the odd object were correct when an oddity problem was presented on a white tray and responses to either of the nonodd objects were correct when presented on a black tray. Given the use of trial-unique discriminanda, specific configuration learning was not possible. Correct responses resulted in a food reinforcer that was accessible from a food well beneath the correctly chosen discriminandum. Object positions and color of tray used on each trial were varied quasi-randomly. All three monkeys met a criterion of 90% correct responses in 20 successive trials. Thomas and Kerr concluded that the monkeys had demonstrated "conceptual conditional discrimination," which would be accurate if only "conditional discrimination" as defined by French (1965) was intended. However, Thomas and Kerr (1976) then made the mistake, as many others have done, when they interpreted their monkeys as having used a biconditional rule analogous to Bourne's (1970) humans subjects' use of a biconditional rule. Unrealized by them, Thomas and Kerr's task did not conform to the truth table for the biconditional or for the conditional.

### The Conjunctive-Conditional Conundrum

Thomas eventually realized that Thomas and Kerr's (1976) findings might be explained best by their monkeys using a conjunctive rule, as

their task was consistent with the truth table for the conjunctive. Nevertheless, even though their task did not conform to the truth table for the conditional, it remained possible that the monkeys were responding according to using a conditional rule; see more on this below.

Thomas's first opportunity to correct the record was in the discussion section of a study by Burdyn and Thomas (1984) who investigated "conditional discrimination" as French (1965) defined it. Burdyn and Thomas tested squirrel monkeys and conceptual simultaneous and conceptual successive discriminanda. Trial-unique exemplars of objects manifesting "sameness" or "difference" were used as the simultaneous discriminanda. The successive discriminanda were exemplars of "triangularity" and "heptagonality" (solid triangles and heptagons drawn on white cards); they used a sufficient number of these discriminanda to render rote memorization of specific triangles and heptagons unlikely. However, again like Thomas and Kerr (1976), while Burdyn's and Thomas's monkeys might have used a conditional rule, the experimental design conformed only to the truth table for a conjunctive rule.

Other investigators have reasoned erroneously that animals performed conditional discrimination tasks by means of propositional reasoning such as a conditional rule [e.g., chapter by Jerre Levy (pp. 157–173) and Terrence Deacon's first of two chapters (pp. 363–381) in Jerison and Jerison (1988)]. Levy and Deacon suggested the significant role that conditional discrimination had in the evolution of language. Levy (p. 164) cited animals' abilities for conditional discrimination as possibly representing "a preadaptation of the simian brain for the evolution of human propositional reasoning," and Deacon (p. 408) referred to the role of conditional discrimination learning in the evolutionary selection for "symbolic communication." Levy based her hypothesis on research by Dewson (e.g., 1977) and Deacon based his on research by Petrides (1987). However, the conditional discrimination experiments by Dewson and Petrides were amenable to rote learning. Dewson made no claims regarding propositional reasoning, but Petrides was clear in his belief that his experiments showed use of a conditional rule; specifically, he referred

to “if-then” reasoning when his task did not conform to the truth table for a conditional rule.

Bourne’s (1970) Fig. 1 (please see Bourne 1970, p. 548 for his Fig. 1) shows how human or animals (Bourne only studied humans) might partition nine discriminanda into correct and incorrect examples using conjunctive, disjunctive, conditional, or biconditional rules. In Bourne’s Fig. 1, there were nine discriminanda based on three colors and three shapes (square, triangle, and circle) where all shapes might be presented in one each of three colors. As his article was in a black and white print journal, “redness” (Bourne’s characterization) was represented when the square, circle, and triangle were drawn with stripes. The other two colors not named in Fig. 1 were represented as black-filled or white-filled squares, circles, and triangles. To illustrate correct versus incorrect partitioning according to conjunctive, disjunctive, conditional, and biconditional truth tables, Bourne used red and square as his focal attributes. These attributes will be the illustrative discriminanda in the truth tables for the conjunctive and the conditional below. The “&” symbol or the word “and” symbolize the conjunctive rule, so  $p \text{ \& } q$  is equivalent to saying “p and q.”

Conjunctive truth table illustrated with discriminanda

| p         | q            | p & q       |
|-----------|--------------|-------------|
| T red     | T square     | T correct   |
| T red     | F not-square | F incorrect |
| F not-red | T square     | F incorrect |
| F not-red | F not-square | F incorrect |

In partitioning, row 1 indicates a discriminandum must be red and square to be a correct exemplar. All other discriminanda are exemplars of incorrect discriminanda.

With the conditional, the “>” symbol or the words “if-then” symbolize the conjunctive rule, so  $p > q$  is equivalent to saying “if p, then q.”

Conditional truth table illustrated with discriminanda

| p         | q            | p > q       |
|-----------|--------------|-------------|
| T red     | T square     | T correct   |
| T red     | F not-square | F incorrect |
| F not-red | T square     | T correct   |
| F not-red | F not-square | T correct   |

In partitioning correct and incorrect discriminanda according to the conditional rule, row 1 shows discriminandum p must be red and discriminandum q must be square to be correct. Row 2 shows that if discriminandum p is red and discriminandum q is not-square, by implication the red triangle and the red circle are incorrect exemplars. Rows 3 and 4 where p is not-red shows there is no constraint against any not-red discriminanda being correct. This writer is unaware of any animal research purporting to study use of the conditional rule that has incorporated into its experimental design ways to test the contingencies in rows 3 and 4. This writer is not confident that a conditional-rule-use-experiment can be designed that could be used successfully with animals, but that is an open question.

Bourne’s (1970) Fig. 1 was for demonstration. His actual testing discriminanda included three colors (red, green, blue), three shapes (square, triangle, circle), three sizes (small, medium, large), and three variations in number; that is, 1, 2, or 3 discriminanda of a given color, shape, and size might be used. For each rule being tested (viz., conjunctive, disjunctive, conditional, or biconditional), the subject was handed a card specifying the pair of relevant attributes being used to partition whether each discriminandum was correct or incorrect. The subject had a two-button device, one for “Correct” and one for “Incorrect” discriminanda according to the rule being used. A light above each button would illuminate if the answer was correct. The subject had to infer the rule over several to many trials based on feedback from the lights whether her/his choice on each trial was correct or incorrect. The criterion for mastery of a given rule was 16 successive correct responses. Based on the number of trials needed to meet criterion, Bourne’s subjects revealed the following order of difficulty where < symbolizes fewer trials

$$\text{Conjunctive} < \text{Disjunctive} < \text{Conditional} < \text{Biconditional}$$

An important part of Bourne’s evidence was the subject’s explanation of the rule that was correctly inferred. Such evidence is not available to animal research investigators.

## Natural or Mental Logic Versus Symbolic or Standard Logic

It would be remiss to fail to consider the long-standing interest by many cognitive scientists in “natural logic” or “mental logic” as opposed to standard truth-table-based logic such as that used in Bourne’s research. Martin D. S. Braine (1926–1996) was among the best-known advocates for “natural” or “mental” logic. Earlier he used the phrase “natural logic” (Braine 1978), and later he preferred the phrase “mental logic” (Braine and O’Brien 1998; this was an edited volume published after Braine’s death in which Braine, O’Brien, and others contributed chapters. This literature is too vast and too complicated to summarize here, but relevant points pertaining to animal research are that (a) Braine and others used only human subjects and verbal tasks, usually in the form of providing the premise of a syllogism where the subjects provided the predicate that they conceived to be appropriate and (b) critical to the evidence were the subjects’ verbal explanations. Neither of those are possible with animals. Perhaps, the most important result of this research for animal researchers is that Braine and others concluded that humans can reason correctly, for example, according to a conditional rule without necessarily using tasks that conformed fully to truth table requirements for a conditional rule.

An important implication for animal research is that it is *possible* that when “conditional discrimination” tasks as defined by French (1965) that involve class concept discriminanda are performed successfully by animals, the animals *might* have used a conditional rule. However, it seems unlikely that tasks to confirm such with animals can ever be constructed. Therefore, unless someone can design an experiment using class concept discriminanda and procedures that conform to either disjunctive or conditional truth-table-based rules, the only conclusive evidence of relational concept learning by animals appears to be limited to using conjunctive rules.

Finally, one can do nothing more than speculate about what neural processes an animal might employ to use conjunctive rules successfully. Referring back to Burdyn’s and Thomas’s (1984)

evidence of squirrel monkeys using conceptual conjunctive rules, a human might verbalize externally or internally that “triangle *and* sameness” go together and that “heptagon *and* difference” go together. One can easily imagine a human verbalizing externally or internally the solution to the same task as “*if* triangle, *then* same” and “*if* heptagon, *then* difference.” A human can explain her/his conceptualization of the task, but unfortunately a monkey cannot. It is baffling to think how a monkey is able to perform a conjunctive task without having language to express it, even if only internally. Dr. Doolittle, we need you!

## Relative Numerousness

Roger K. Thomas  
Department of Psychology, University of  
Georgia, Athens, GA, USA

## Introduction

Stevens (1951, p. 22) distinguished between numerosity and numerousness. Numerosity referred to the determination of the cardinal number of a set of objects by counting, and numerousness referred to the determination of the cardinal number for a set of objects by a method other than counting. Stevens' distinction is used here, although many investigators do not, and they often use numerosity in instances where numerousness should be used.

## What is Counting?

Counting research involving children and non-human animals usually relies on whether the child or animal has met the requisite number of Gelman and Gallistel's (1978) five principles of counting. In order as listed, the five principles are:

1. Stable Order – say you have five apples, you must always count them in the same order (e.g., 1–2–3–4–5).
2. One-to One Correspondence – each object receives one and only one count. Gelman and Gallistel also wrote that “tagging” each object with a unique tag was a part of this principle (again, e.g., “1,” “2,” “3,” “4,” “5”).
3. Cardinality – the last tag correctly applied represents the quantity for that set of objects.
4. Abstraction – the ability to count any set of objects, e.g., apples, oranges, cows.
5. Order Irrelevance – using the example of five apples side by side. You may start at either end, in the middle, etc. but you must count each apple only once and end with the correct cardinal number of apples.

Most investigators, including Gelman and Gallistel, consider that if the first three principles are met, one has provided evidence that the child or animal can count.

In most animal research, it is questionable whether an animal has learned the necessary tags to be able to count. Perhaps, research from the laboratories of Sarah Boysen, Duane Rumbaugh, and Tetsuro Matsuzawa has come the closest; all studied chimpanzees. Most animal research associated with animals' use of number has not involved counting as no tagging system is used. An alternative process to counting that most animals likely use will be described below.

Interest in animals' use of number achieved prominence in the early twentieth century with well-known research on “Clever Hans,” the counting horse. Eventually, it was determined that Hans's apparently successful performances were based on inadvertent cues by his owner

and that gave birth to the need to prevent “Clever Hans cues” in animal learning and cognition research.

## Ecological Salience of Numerousness

James Lipton (1991) is a modern authority on nouns of assembly (e.g., a gaggle of geese, a colony of ants, a flock of sheep). Lipton reported that the earliest known list was *The Edgerton Manuscript* (circa 1450), and the best known of the early compilations was the *Book of Saint Albans* (1486). Most nouns of assembly were associated with game and domestic animals, but humans as well (e.g., a den of thieves). The history of nouns of assembly shows the long-time interest in the uncounted numerousness of animals. In some cases, a noun of assembly was shared by several species, such as “herd” or “flock.”

Numerousness has ecological salience for many animals. For example, the monkey in a group of monkeys feeding competitively that first detects several bushes of edible fruit is likely to go first to the bush perceived to hold the most fruit and, with clusters of fruit on a single bush, is likely to go for the cluster with the most fruit. A predator, such as a lion, that feeds on prey that depend on escape for defense such as wildebeests, will be more successful by attacking a large group, as it will be more likely to yield a young, weak, or lame wildebeest. Leopards that prey upon baboons will seek a smaller group to attack, as baboons in significant numbers are more likely to fend off the predator. The numbers of eggs and hatchlings for most nesting birds or the number of offspring for other animals giving multiparous birth likely find numerousness salient. Imagine the mother with multiple altricial offspring trying to keep an account of the proximity of her young. Of course, it seems unlikely that any of these animals meet Gelman and Gallistel's (1978) prerequisites for counting, especially that of having a “tagging system.” So what might they use to process number?

## Processes Used to Determine Numerousness

Davis and Perussé (1988) presented an ambitious glossary of numerical processes. In the following order, Davis and Perussé's glossary included (a) Relative numerousness judgments, (b) Subitizing, (c) Estimation, and (d) Counting, which they further divided into (e) Protocounting and (f) Concept of number.

Thomas and Lorden (1993) countered that only three types of numerical processes were necessary: (a) absolute numerousness judgments, (b) relative numerousness judgments, and (c) counting. See Thomas and Lorden (1993) for reasons why they disagreed with Davis and Perussé's glossary.

Absolute numerous judgments by squirrel monkeys were investigated by Thomas et al. (1980). They used cards with black-filled circles (hereafter "dots") and all the appropriate controls. After lengthy, intermingled stepwise training and testing, their two squirrel monkeys learned to discriminate seven from eight dots; one monkey discriminated eight from nine dots. Thus, both monkeys learned that "sevenness" was different from "eightness." The monkeys could not count the dots as they had no opportunity to learn a "tagging system" (see "[What is Counting?](#)" above).

With practice, humans may become adept at accurately and immediately perceiving as many as seven or eight dots. Thomas et al. (1999) showed that most humans tested could identify sevenness and eightness under conditions that prevented counting. A few were accurate with higher numbers. The upper limit may be related to G. A. Miller's well-known "magical number seven, plus or minus two," which Miller said specified the limits of unidimensional information processing; see discussion in Thomas et al. (1999).

Children and adults, especially in Western cultures, have considerable experience recognizing numerousness accurately without counting. Consider the number of dots on the six faces of dice used in many board games. Most will recognize the number of dots (1 – 6) on the top

face without counting, and if two dice are used, most will immediately perceive the sum of the dots on the two top faces. This ability can be acquired with less fixed patterns. For example, if you approach a bus stop with three people waiting, you will likely perceive "three" without counting them. If a group of four birds flew overhead, you will likely perceive "four" without counting. If you saw five sheep grazing, in a cluster, you will likely perceive "five" without counting, and when in doubt, one may easily count them. Go out and see for yourself whether you can immediately perceive low numbers of objects, animals, people in clusters, etc. without counting and whether with practice, as in the Thomas et al. (1999) study, you can learn to perceive as many as eight objects without counting.

Making relative numerous judgments without counting is usually easier if you do not need to know the exact numbers. For example, if driving along a country road, you see a small pasture on the left with 20 cows and, on the right, you see a similarly small pasture with 50 cows, you likely perceive immediately that there are more cows on the right. Smaller differences might be perceived immediately, say 20 versus 30 cows, but 20 versus 23 cows might require counting. Later, an experiment that investigated relative numerous judgments by squirrel monkeys will be described.

## Prototype Matching

Inspired by Rosch (1975), Thomas and Lorden (1993) proposed that accurate perception of numerousness is done by prototype matching. Among other semantic categories, Rosch used 53 species of birds (and the mammal, bat; see page 232) as examples of the category "Bird." For her American students, the best prototype of a bird was the American robin; the penguin and the bat were deemed to be farthest from the prototypical robin. Based on research by Thomas et al. (1980), Thomas and Lorden concluded that squirrel monkeys acquired prototypes

for as many as eight discriminanda. Thomas et al. (1999) extended that conclusion to humans.

## Conceptual Relative Numerousness Judgments

Apparently, the first published study using animals (three squirrel monkeys) to demonstrate the ability to make conceptual relative numerosness judgments was by Thomas and Chase (1980). Like Thomas et al. (1980), they also used “dot” cards as discriminanda, and they used all the appropriate controls. Three cards were presented on a platform. The monkey responded by pushing aside a card holder that exposed a food well. If it was correct, a food reinforcer (a currant) was easily accessible from the food well. On the front of the platform was a row of three 25-watt, neon panel lamps. If all lamps were illuminated, the correct response was to choose the card with the highest number of dots. If the two end lamps were illuminated, the correct response was to choose the card with the intermediate number of dots, and if only the single center lamp was illuminated, the correct response was to choose the card with the fewest dots. Position (left, center or right) of the card bearing the correct numerosness card was randomized.

Sixteen intermingled training and testing steps were used. In order, the most definitive steps were to learn to (a) choose the highest number when three lamps were on, (b) choose the intermediate number when two lamps were on, (c) choose between random presentations of highest and intermediate numbers according to the cue lights, (d) choose the lowest number when one lamp was on, and (f) choose among the highest, intermediate, and lowest dot-number cards presented in random order and consistent with the cue lights. One monkey succeeded on the final step; that is, it could choose correctly the card with the highest, intermediate, or lowest number of dots as cued by the lights. Another monkey was able to choose correctly between highest and intermediate numbers of dots presented randomly, but the third monkey learned only to choose the most dots. Nevertheless, all monkeys showed some

ability to respond to relative numerosness conceptually, and the best monkey’s performance indicated that it made ordinal judgments involving relative numerosness.

## Concluding Remarks

Animals including humans accurately identify as many as eight discriminanda without counting. They do this by acquiring prototypes (“fourness,” “eightness,” etc.) and applying them accurately. Relative numerosness is judged easily when two or more sets of discriminanda are sufficiently different in number and are distinctly clustered.

Because at least two squirrel monkeys in Thomas and Chase’s (1980) study learned to choose the intermediate-in-numerosness set of discriminanda when three sets (most, intermediate, and fewest) were presented concurrently, Thomas and Chase (1980) also concluded that squirrel monkeys learned “ordinal numerosness judgments,” a higher-order example of relative numerosness judgments.

However, subsequent researchers have not followed Thomas and Chase’s condition that ordinal judgments should be based on a minimum of three sets of numerosness discriminanda being presented concurrently, and some investigators refer to their animals having made “ordinal judgments” when only two sets of discriminanda were presented (e.g., Olthof et al. 1997, who tested squirrel monkeys; Washburn and Rumbaugh 1991, who tested rhesus monkeys).

However, Beran et al. (2005) conducted a clever experiment testing two chimpanzees and a rhesus monkey. They began their article by quoting Brannon’s (2002) definition of “ordinality.”

*Ordinality* refers to the relative position of one entity with respect to other entities in a sequence. . . an understanding of ordinality implies not only differentiating two sets of objects or symbols from each other but also knowing what set or symbol is numerically larger or smaller (Brannon 2002; Beran et al. 2005, p. 351).

However, Beran et al. went beyond Brannon’s definition and used five differently colored plastic

eggs, each covering a different number of identical food items. Initially, only two eggs were presented at a time, but eventually trials were presented with three, four or five eggs, and the primates were able to choose the eggs in the order that covered the most food items, the next-most, etc., which indicates that the primates had learned the optimal order of the egg-color, food-items relationship.

## Introduction

Nearly half of the human genome is comprised of repeat sequences. Once thought to be parasitic “junk” DNA, decades of research have revealed some of this repetitive sequence is under selection, and much of it is involved in biochemical activities (ENCODE 2012). Genomic repeat sequences can be divided into two large categories: noncoding tandem repeats (interstitial TTAGGG sequences or ITSs, and satellite DNAs) and transposable elements (including short interspersed nuclear elements or SINEs, long interspersed nuclear elements or LINES, long terminal repeats or LTRs, and DNA transposons) (Tomilin 2008).

There are numerous nuclear mechanisms in place to silence the mobility of transposable elements (TEs), and via genetic drift the majority of TEs have lost the ability to mobilize. However, there is growing evidence for exaptation of TEs as promoters/enhancers that drive expression of endogenous host genes. Some of these TE derived regulatory sequences are bound by tissue-specific transcription factors and are therefore likely to contribute to cell differentiation in embryo development.

Despite the many evolutionary adapted advantages, TEs still pose a threat for inducing or contributing to disease phenotypes. TEs can cause mutations from new insertions and lead to rearrangements of chromosomes. This in turn can lead to cancers, autoimmune disorders, and other diseases, many of which have been shown to have upregulated levels of TEs – the mechanisms that lead to this phenomenon are not well understood.

## Long Interspersed Nuclear Elements (LINES)

LINES are a class of retrotransposons that make up ~21% of the human genome. Full-length LINES are around 6000–7000 base pairs long, and functional LINES work by generating an mRNA that can be translated into a reverse

transcriptase (RT) protein. This protein then converts its RNA into DNA and integrates it into the genome at a new site; however, most LINES are now functionally inactive, at least in terms of the conventional RT pathway. There are three main classes – LINE1, LINE2, and LINE3 – of human LINES. A nontruncated LINE1 element contains two flanking untranslated regions (UTRs) and two open reading frames (ORFs). One of these ORFs contains the RT protein as well as an endonuclease able to cut open DNA (which is necessary for integration) (Rodić and Burns 2013).

Most genomic copies of LINES are inactive due to a 5' DNA truncation that cause a loss of the RNA polymerase II promoter located in LINES. In humans, however, LINES are still retrotranspositionally active in the germ line, with estimates of 1 new LINE insertion per 95 live births (Huang et al. 2012). Thus, there is a large amount of LINE1 polymorphism in the human population. LINES are also active in somatic cells, most notably in neural stem cells, which contributes to genetic mosaicism in the human brain. To prevent mobility, LINE1 elements are therefore silenced by various transcription factors, which in turn silences nearby genes and promote methylation in these areas. Subsequently, LINE1 elements are typically found in gene poor sections of the genome and are thought to contribute to the compartmentalization of the genome via the segregation of these silenced domains of genes. Other proposed functions of LINE1 elements include establishing a chromatin state for Xist to induce X chromosome inactivation (Chow et al. 2010), a binding site for various transcription factors that have both positive and negative regulatory effects, and acting as the nuclear machinery (the RT and endonuclease protein) for propagating short interspersed nuclear elements. LINE1 expression is also shown to be upregulated in human cancers and may be a useful marker for detecting cancers in the future (Rodić et al. 2014).

## Short Interspersed Nuclear Elements (SINEs)

SINEs are another type of retrotransposon – they make up around 13% of the genome. They are under 600 base pairs in size. As SINEs do not

translate into protein (they are only transcribed into RNA), they do not encode for RT or any endonuclease activity. SINEs are dependent on other TEs (usually LINE1 elements) to reintegrate into the genome. The Alu family of SINE elements is the most abundant retroelement in the human genome. Alu elements contain a 5' sense facing RNA polymerase III promoter, which is followed by an adenine rich region that is surrounded by repeats derived from initial insertion events. The 3' end of the sequence has a stretch of adenines and is variable in length (Batzer and Deininger 2002).

SINEs are derived from genes transcribed by RNA polymerase III (like transfer RNA). This, however, is not sufficient for initiating transcription – other neighboring sequences are necessary. SINEs have also been potentially linked as a mechanism for increasing genetic diversity as they act as sites for homologous recombination – this occurs due to their repeat regions.

Some SINEs contain binding sequences for transcription factors associated with higher order genomic organization, such as CTCF (Chuong et al. 2017). SINEs are highly enriched around “active” areas in the genome. Alu elements, like many SINEs, are found in gene-rich sections of the genome and specifically near promoters of active genes. Alu elements protect these active regions from the spread of DNA methylation; this phenomenon is tissue-specific, allowing for a mechanism to turn genes on and off (Batzer and Deininger 2002; Tomilin 2008).

The role of SINEs is varied; from being boundaries for areas of active genes, to tissue-specific gene regulatory function, to hot spots for

recombination events, SINE elements have evolved to help organize genomic content.

## Long Terminal Repeats

Long terminal repeats (LTRs) are repetitive sequences found in the genome. They are derived from endogenous retroviruses (ERVs) although their modern structure is different. Together, ERVs and their remnant parts make up 8% of the genome. The traditional sequence of an integrated retrovirus, called a provirus, is a coding region comprised of the *Gag*, *Pol*, and *Env* genes (Yu et al. 2013). These are responsible for encoding the capsid (the protein structure that holds the genetic content), replicating the viral genetic content and integrating it into the host's genome, and the protein able to enter the host cell, respectively. Those genes are flanked by LTRs on either side, which contain promoter, enhancer, and polyA signals, and also help integrate the viral content into the genome. Most ERVs have undergone recombination between 5' and 3' LTRs during the course of evolution and lost the coding region, leaving primarily “solo” LTRs throughout the genome (Chuong et al. 2017).

These LTRs now act as promoters, enhancers, and poly adenylation sites for other genes. Many LTRs function in a tissue-specific capacity (via acting as transcription factor binding sites) and are most highly active during embryogenesis. Finally, LTRs can play a role in disease phenotypes (such as tumors) by regulating oncogenes or through recombination events (Yu et al. 2013) (Fig. 1).

**Repeat Sequences, Fig. 1** An example of repeat elements acting in a cis-regulatory fashion. Short interspersed nuclear elements (SINEs) are making boundaries around

an active gene, while a long terminal repeat (LTR) is acting as an enhancer

## DNA Transposons

DNA transposons are a type of repeat element that mobilize via a cut-and-paste mechanism, with only a DNA intermediate. DNA transposons encode a transposase protein, which is responsible for the movement of the gene (the cut-and-paste activity); some DNA transposons also are known for encoding genes not related to transposition. This protein coding sequence is flanked by terminal inverted repeats, which are needed for the insertion function of the transposase protein. The number of transposition events among members of a species can vary greatly. Over the course of time, this can lead to numerous evolutionary events. Thought to be drivers of evolution throughout different species, DNA transposons can undergo partial transposition events, which can cause large chromosomal rearrangements (Feschotte and Pritham 2007).

DNA transposons can alter the host genome in a number of ways, some unique from other retrotransposons. Obviously they can cause mutations by inserting into a gene, but they can also insert in promoters, introns, enhancers, and other genomic regions causing a myriad of epigenetic outcomes. Unlike other retrotransposons, DNA transposons can excise themselves and jump to nearby sites; therefore, some phenotypes are reversible. Due to the association of repressive histone marks, DNA transposons have also been linked as moveable pieces in silencing heterochromatin. Finally, DNA transposons have also been domesticated for a number of critical host functions, including the recombination-activating genes (RAGs), which mediate VDJ recombination, a process that increases the diversity in the immune system (Feschotte and Pritham 2007).

## Conclusion

At least 16% of conserved noncoding regions across mammalian genomes are found in transposable elements, indicating a key role in the evolution of gene regulation (Tomilin 2008). With nearly 48% of the genome made up of these repeat elements, it is unsurprising that they

have become a necessity to the genome. Many act as tissue-specific regulatory elements, either as promoters, enhancers, or boundary elements. Often they act in unison – LTRs and SINEs can contribute to a similar developmental gene networks, such as HPAT5 (an essential gene for inner cell mass development), a transcript made from an Alu SINE and an ERV (Chuong et al. 2017). While there is still much to learn about the role that repeat elements play in the genome, their generalized function as genomic organizers has become accepted by the larger scientific community.

## Definition

Reproduction is a process by which organisms replicate themselves. In a general sense, reproduction is one of the most important concepts in biology: it means making a copy, a likeness, and thereby providing for the continued existence of species. Although reproduction is often considered solely in terms of the production of offspring in animals and plants, the more general meaning has far greater significance to living organisms. To appreciate this fact, the origin of life and the evolution of organisms must be considered. One of the first characteristics of life that emerged in primeval times must have been the ability of some primitive chemical system to make copies of itself. At its lowest level, therefore, reproduction is chemical replication. As evolution progressed, cells of successively higher levels of complexity must have arisen, and it was

absolutely essential that they had the ability to make likenesses of themselves. In unicellular organisms, the ability of one cell to reproduce itself means the reproduction of a new individual; in multicellular organisms, however, it means growth and regeneration. Multicellular organisms also reproduce in the strict sense of the term – that is, they make copies of themselves in the form of offspring – but they do so in a variety of ways, many involving complex organs and elaborate hormonal mechanisms.

## Introduction

Reproduction is important for the survival of all living things. Without a mechanism for reproduction, life would come to an end. There are basically two types of reproduction in a broad sense, asexual and sexual reproduction. The term asexual reproduction refers to simple cell division that produces an exact duplicate of an organism (Billing et al. 1995). There are many different types of asexual reproduction which can be discussed to show students the variability of modes of reproduction. Some single-celled organisms reproduce by simple cell division – this is called binary fission. In this manner, the mother cell simply splits in half producing two daughter cells. Some cells reproduce by unequal division of the cells – this is called budding. In this process the bud forms as a knob on the mother cell. The nucleus divides, and identical parts go to the mother cell and the bud. The bud may grow until it is as large as the mother cell and can form buds of its own. In some cases buds remain attached to the mother cell. In others, they break away and live as separate organisms. On the other hand, sexual reproduction involves the joining of male and female sex cells. The sperm refers to the male sex cell, and the egg refers to the female sex cell.

## Reproduction Types

Living organisms reproduce in two ways – asexual and sexual reproduction.

### Asexual Reproduction

Asexual reproduction involves the production of an offspring from body parts other than the reproductive organs. It is a common process of reproduction in lower plants and animals.

The following are the basic features of asexual reproduction:

- (i) It involves only one organism, i.e., different sexes are not involved.
- (ii) The cell divisions during this type of reproduction are either mitotic or amitotic.
- (iii) New individuals produced are genetically identical to the single parent.
- (iv) It is a fast mode of multiplication.

There are different types.

#### Fission

Fission is of two types: binary fission and multiple fission. In binary fission, two individuals are formed from a single parent. This type of reproduction is found in organisms like bacteria, yeast, and amoeba.

#### Multiple Fission

In multiple fission, many individuals are formed from a single parent. This type of reproduction by multiple fission occurs during unfavorable conditions.

#### Budding

In this type of reproduction, a bulb-like projection or outgrowth arises from the parent body known as bud, which detaches and forms a new organism.

**Regeneration or Fragmentation** In this type of reproduction, the body of an individual breaks up into two or more parts, and each part develops into a complete individual, for example, *Spirogyra* and *Planaria*.

**Spore Formation** In lower forms of life like the alga, *Chlamydomonas*, the protoplast of the cell divides to form 4–8 spores. These being motile are termed as zoospores. When spores are released

in the surrounding medium, they develop into new plants.

**Vegetative Propagation or Vegetative Reproduction** Vegetative reproduction (or vegetative propagation) is a form of asexual reproduction in plants in which a bud grows and develops into a new plant. In this type of reproduction, any vegetative part of the plant body like leaf, stem, or root develops into a complete new plant. Vegetative reproduction can take place by two methods – natural and artificial.

### **Sexual Reproduction in Plants**

In flowering plants, the flower is the reproductive part of a plant. Most flowers have both male and female reproductive organs. They include pollination and fertilization.

## **Animal Reproduction**

### **Female Reproductive System**

The ovary, or female gonad, is the primary organ of reproduction in the female and is responsible for two basic functions: production of the female gamete and production of two primary reproductive hormones, estrogen and progesterone. For example, a cow has two bean-shaped ovaries that are around 3 cm long and are suspended from the broad ligament near the end of the oviducts. The size of the ovaries varies with the stage of the reproductive cycle and age of the female. The ovary consists of an inner part, the medulla, and an outer part, the cortex. The medulla part contains blood vessels, nerves, and connective tissue. The cortex part contains the germinal epithelium and produces the ovum by a cyclic process called oogenesis (Valerie 2006).

#### **The Ovary**

The ovary contains several thousand tiny structures called primary follicles. Each primary follicle consists of a germ cell surrounded by a layer of cells. This germ cell has the potential to mature into an ovum if the follicle completes development (known as the Graafian follicle). However,

most of the primary follicles never develop. Rather, they die and are absorbed by the ovary and replaced by newly formed primary follicles. So a cow will generally ovulate less than 100 since only one ovum is released at each cycle. By the injection of hormones, a cow can be induced to release more than one ovum at each estrous cycle. This technical is used in embryo transfer. After puberty a Graafian follicle is generally produced every 21 days until the cow becomes pregnant. The Graafian follicle can be palpated through the rectal wall. At maturity the ovum and follicular fluid are released from the ovary in the process called ovulation. After ovulation the wall of the follicle collapses and forms the corpus luteum, commonly referred to as CL or yellow body. The yellow body gets its name from its deep yellow color in the cow due to the presence of  $\beta$ -carotene.

#### **The Oviduct**

The oviduct begins as a funnel-shaped tube that engulfs the ovary. This funnel portion of the oviduct is called the infundibulum. When ovulation occurs, the ovum is picked up by the infundibulum and channeled into the oviduct (also called Fallopian tube), where fertilization takes place if viable sperm were present. The infundibulum has a fringed border, the fimbria, which helps to pick up the ovum from the ovary. Into the oviduct the ovum remains capable of fertilization for only a short time. Thus it is essential that sperm be present in the oviduct near the time of ovulation. The ovum moves through the oviduct into the uterine horn within the next three to four days. If the ovum is fertilized, it then begins embryological development; if not, it degenerates and disappears, and the next estrous cycle ensues.

#### **The Uterus**

The uterus consists of two parts, the body and horns. The uterus is suspended from the broad ligaments. The body of the uterus of the cow is short and poorly developed, while the uterine horns are relatively long and well developed. The developing of the fetus takes place in the

uterine horns. During most artificial insemination procedures, semen is placed in the body of the uterus. If semen is placed in the horn opposite the ovary from which the ovum was released, the chances of fertilization are very low.

### The Embryo

The fertilized embryo moves from the oviduct into the uterine horn, where fetal and maternal membrane development begins. This newly developing fetus grows within a layer of membranes called the placenta. There is no direct blood connection between the fetus and the dam but rather a complex system that selectively allows certain molecules to pass from the maternal side of the placenta to the fetal side and vice versa. It also provides nutrients and carries waste products from the fetus. The endometrium (lining) of the uterus becomes very vascular after fertilization, in preparation for the implantation of the fertilized ovum. The uterus develops the maternal side of the placenta to protect and nourish the developing fetus. The caruncles (about 100) of the uterine endometrium interlock with the cotyledons of the fetal placenta and provide a passageway for the nutrients from the cow to the fetus and for the waste products to be removed from the fetus. Villi of the embryonic cotyledons fit into crypts of the maternal caruncles to form placentomes, the functional units of exchange. The developing embryo sets up its own placental membranes, which consist of the chorion (outer membrane), the amnion, the yolk sac, and the allantois. The amnion contains a cavity that surrounds the embryo and becomes filled with liquid that serves as a protective cushion to the fetus. The yolk sac supplies nutrients to the fetus during early development but functions for only a short period of time. The chorion contains a rich source of blood vessels and gives rise to the cotyledons. The allantois is an outpouching of the hind gut of the fetus and serves as a urinary receptacle for the fetus.

### The Cervix

The cervix is a thick-walled structure about 10–11 cm long and 2.5–5 cm in diameter located between the uterine body and the vagina. In effect

the cervix is the neck of the uterus. The cervix contains ridges called annular folds. These folds must be manipulated through the wall of the rectum during artificial insemination in order to pass the insemination rod into the uterus. An opening in the cervix, through the annular folds, allows a passageway for sperm at mating (or insemination rod) and expulsion of the fetus at the time of birth. The cervix produces a mucus secretion that is usually thick; however this secretion is fluidized at the time of estrus to facilitate the movement of sperm to the uterus. This fluid can be seen as part of the discharge from the vulva at estrus. During pregnancy, the thick mucus secretion is called cervical plug, which protects the uterus from infections entering from the vagina. The cervical plug is expelled, and the cervical opening begins to dilate in the days prior to calving. So the major function of the cervix is to restrict access to the uterus. The cervix and its secretions thus form a physical barrier and protect the uterus against microorganisms (bacteria, virus) and other foreign material.

### The Vagina

The vagina, which is about 18 cm long and located between the cervix and the vulva, serves as a receptacle for the penis during service. In the cow, the semen is deposited in the vagina near the cervix during natural mating with the bull. When artificial insemination is used, the insemination rod is threaded through the vagina and cervix, and semen is deposited at the uterine side of the cervix. In addition, the vagina serves as a birth canal during parturition. The vaginal epithelium secretes fluids, which, along with the fluids of the cervix, inhibit growth of bacteria and thus provide a line of defense against bacteria invasion of the uterus. Urine is discharged from the urinary bladder through the urethra, which opens into the base of the vagina. The region behind the urethral opening is called the vestibule and is a common passageway for both the urinary and reproductive systems. Care must be taken during artificial insemination because the insemination rod can be introduced into the urethral opening. The vulva forms the external opening of the reproductive tract and consists of thickened folds of skin

(vaginal lips). The vulva is sensitive to changes in blood estrogen, which causes an increase in blood flow to the vulva and results in redness and swelling. These signs can be a help in estrus detection.

### Male Reproductive System

The primary organ of reproduction in the male is the testicles, of which the bull has two, as is the case in most animals. Secondary sex organs and three accessory sex glands are part of reproductive male tracts. All reproductive organs work in concert for formation, maturation, and transport of spermatozoa, which are eventually deposited in the female reproductive tract. The secondary sex organs are the epididymis, vas deferens, and penis. The three accessory sex glands include the seminal vesicles, prostate, and bulbourethral gland (Chakraborty et al. 2016).

#### The Testicles

The testicles are located outside the body cavity in the scrotum (external oval sac) and have two vital functions: producing the spermatozoa and producing the testosterone (male hormone). Location of the testicles exterior to the body cavity is essential for normal sperm formation, which occurs only at 1–4 °C cooler than body temperature. The scrotum provides physical protection to the testicle and helps regulate the temperature for optimum spermatozoa development. This regulation is done by coordination of three structures: a temperature-sensitive layer of muscle (tunica dartos) located in the walls of the scrotum, which relaxes when hot and contracts when cold; the external cremaster muscle within the spermatic cord, which controls the proximity of the testicle to the body by lengthening or shortening depending on environmental temperature; and a counter-current temperature exchange regulated by a blood flow process known as the pampiniform plexus, which is a coil of testicular veins that provide an effective mechanism for cooling arterial blood entering the testicle and transferring its heat to the venous blood leaving the testicle. One or both testicles occasionally fail to descend into the scrotum during embryological development and are retained in the body cavity.

This condition is known as cryptorchidism. Hormone production by cryptorchid males is near normal, and the male develops and behaves like a normal male however will generally be subfertile. This condition is genetically inherited; therefore such males should not be used for breeding. The seminiferous tubules are lined with germinal epithelium, the spermatogonia. The seminiferous tubes are formed by many long, tiny, coiled tubes, within which the sperm are produced and begin to mature. Specialized cells, known as Sertoli cells, localized in the seminiferous tubes are responsible to provide nutrients to the spermatozoa. Scattered throughout the loose connective tissue surrounding the seminiferous tubules are other kind of specialized cells, the interstitial cells of Leydig, which produce testosterone. There are hundreds of individual seminiferous tubules in the body of the testicle which unite with one another to form a few dozen tubules that exit from the testicle and pass into the epididymis (Guraya 1987).

#### The Epididymis

The epididymis is a compact, flat, elongated structure closely attached to one side of the testicle. It is divided into three regions, the head, body, and tail. The many tubules enter the head of the epididymis from the testicle and unite to form a single tubule. An epididymis bull has approximately 35 meters long, and this tubule is convoluted and packed into 18 cm. Four major functions occur in the epididymis, including the transport of the developing sperm cells from the testicle to the vas deferens; the concentration of the sperm by absorption of surplus fluids; the maturation of the developing spermatozoa; and the storage of viable sperm cells in the epididymis tail. If sexual activity is slowed, resorption of sperm cells from the epididymis tail occurs. The epididymis serves as an outlet for all the sperm produced in the testicle, and any blockage of this tube will cause sterility. Temporary blockage due to swelling following an injury or infection (epididymitis) will result in short-term infertility. If the swelling or infection results in formation of scar tissue in the tubule, it may permanently block the passage of sperm. If blockage occurs in both epididymides, the

bull will no longer be useful as a breeder. Surgical removal of the tail of the epididymis (epididymectomy) is frequently used as a means of sterilization for teaser (Gomer) bulls for estrus detection. Epididymectomized bulls will mate cows in the usual manner, because they still produce testosterone from cells of Leydig, however will not deposit sperm in the female reproductive tract.

#### The vas Deferens

The vas deferens, also known as ductus deferens, emerges from the tail of the epididymis as a straight tubule and passes as part of the spermatic cord through the inguinal ring into the body cavity. Spermatozoa are transported further along the reproductive tract to the pelvic region through the vas deferens by contraction of the smooth muscle tissue surrounding this tubule during ejaculation. Bulls may also be sterilized by vasectomy in which a section of the vas deferens is removed so that sperm cannot pass to urethra and go outside of the body. The urethra is a single tube that communicates with two vasa deferentia. Anatomically the urethra is the channel passing through the penis. The urethra serves as a common passageway for semen from the reproductive tract and urine from the urinary tract. As mentioned above, the bull has three sets of accessory glands. Semen is made up of fluids from the accessory glands and the sperm (mature spermatozoa). The volume of ejaculate is very variable, 1–15 ml. The concentration will also vary considerably; however the usual is 1–1.8 billion sperm per ml. Since only one sperm is required to fertilize an ovum, considerable dilution of the semen can be done.

Two of the accessory glands, the seminal vesicles and prostate, are located in the region where the vasa deferentia unite to become the urethra. Secretions from these glands make up most of the liquid portion of the semen. In addition, the secretions activate the sperm to become motile. The seminal vesicles consist of two lobes about 10 cm long in the bull, each connected to the urethra by a duct, which the main role is the production of nutrients for spermatozoa. The prostate gland is located at the neck of the urinary

bladder where it empties into the urethra. The prostate is relatively small in the bull, as compared to other species, and does not produce a very large volume secretion, which is rich in enzymes for spermatozoa metabolism.

The third accessory gland, the Cowper's glands, is small, firm glands located on either side of the urethra. The clear and buffered secretion that often drips from the penis during sexual excitement prior to service is largely produced by these glands and serves to flush and cleanse the urethra of any urine residue that may be harmful to spermatozoa. The secretion from Cowper's glands assures an optimizer pH for the semen. This is a protection against an eventual low pH of female reproductive tracts and pH decrease due the spermatozoa metabolism. One of the accessory glands may occasionally become infected, resulting in semen samples that are yellow and cloudy and which contain puss cells. It is not uncommon in bulls for the seminal vesicles to be so affected (seminal vesiculitis). Antibiotic treatment is sometimes necessary, but time will generally correct the problem.

#### The Penis

The penis of bulls has sigmoid flexure. This is an anatomical structure that provides a means by which the penis is held inside the sheath except during time of mate. Strong retractor muscles hold the penis in the "S"-shaped configuration. Occasionally these muscles are too weak to function properly, and a portion of the penis and sheath lining protrude at all times. This exposes the male to the danger of injury, and this characteristic should be avoided when selecting a herd bull. The penis is the organ of insemination. Spongy-type material within the penis is filled with blood during sexual arousal, resulting in erection of the organ. The end of the penis is the glans penis and is richly supplied nerves, which are stimulated during copulation to induce ejaculation. The normal functions of male reproduction are largely controlled by hormones that are secreted from the endocrine glands. The testicle functions as an endocrine gland because of its production of the male hormone, testosterone, by the interstitial cells (cells of Leydig). The

major functions of testosterone are as follows: It is largely responsible for development and maintenance of the male reproductive tract; it causes the development and maintenance of the secondary sex characteristics associated with masculinity, such as the crest and heavily muscled shoulders of a bull; it is a major factor in the normal sex drive and behavior of the male; it increases muscular and skeletal growth; and it is essential for normal sperm formation. The same gonadotropic hormones that regulate ovarian functions in the cow also regulate testicular functions in the bull. LH and FSH are released from the pituitary gland and cause the testicle to secrete testosterone, which then acts on the germ cell lining of the seminiferous tubules to stimulate formation of primordial sperm cells (Chandra and Chakraborty 2017). The maturation of spermatids into fully developed sperm cells requires the presence of FSH. Normal functioning of the male accessory glands requires testosterone. Not only is hormone production of the testicle regulated by hormones released by the anterior pituitary, but the reverse is also true. The level of testosterone in the blood regulates the secretion of gonadotropic hormones from the anterior pituitary via a feedback system. A proper balance of all hormones is vital to successful reproductive functions.

## Conclusion

Reproduction is the basis of life, and this chapter provides a thorough understanding of all the basic and applied aspects of reproductive physiology ranging from plants to higher mammals.

Reproductive success

## Definition

Reproductive fitness reflects the ability of an individual to pass on its genes to the subsequent generations (Kosova et al. 2010).

## Survival of the Fittest

Every species has two major aims: food and reproduction. Food availability and reproduction are so intricately linked that a number of species chose their breeding season according to the food availability. As soon as food is secured, reproduction is the next aim to ensure survival of the species. The term **survival of the fittest** is one of the most prophetic ideas, originally coined by Herbert Spencer after reading Charles Darwin's work. It gained more popularity when Darwin used it in the fifth edition (published in 1869) of the book, *On the Origin of Species*. Survival of the fittest is basically an interchangeable expression to Darwin's "natural selection." The phrase suggested that the organisms that are best acclimatized to their environment are most efficacious in survival and reproduction. However, this glib term often obscures a more precise explanation of evolution. In terms of evolution, "fitness" simply corresponds to the **reproductive success** and reflects how well an organism is adapted to its environment. In other words, it also describes the genetic contribution of an individual to the future generations (Zietsch et al. 2014). Thus, in the evolutionary theory, fitness is a shorthand for "ability to survive and reproduce" (Hansen 2018). The reproductive fitness reflects the potential of an individual to pass on its genes to the subsequent generations. Fitness traits, also referred to as the life-history traits, integrate measures of fertility and mortality and are intricate phenotypes that are direct targets of Darwinian selection (Kosova et al. 2010).

## Absolute and Relative Fitness

There are different ways in which fitness can be measured; for example, **absolute fitness** basically

measures the number of offsprings contributed to the next generation. Absolute fitness is ascribed to a genotype's expected total fitness. Relative fitness is rather a comparative term and is an indication of an allele's or genotype's fitness compared to the maximum fitness. Therefore, **relative fitness** measures differential reproductive success. The term "differential reproductive success" often in statistical terms refers to the comparison of successful reproduction rates between various individual members or groups within generations of a species. If there are two groups, with each group having different variations of the same trait, then determining the differential reproductive success rate will provide an indication of the "fittest" group among them.

Let us understand it with the help of an example; suppose, there are two variants, X and Y, of the same trait. Variation X of a trait reaches the reproductive age more frequently and produces more number of offsprings than variation Y, then estimation of differential reproductive success rate means that variation X is able to dispense more of the genetic material to the next generation and has a greater potential to preserve and deliver it to the future generations. Quite the reverse, variation Y will be more liable to gradually disappear.

Here, it is important to note that the natural selection operates by differential reproductive success of individuals and if the characters that affect reproductive success are not heritable, evolution will no longer occur. Besides, the process of natural selection entails that genotypes must differ in fitness. Without variances in fitness, natural selection cannot act and adaptation cannot ensue (Orr 2009). Furthermore, a longer life span is favored by the natural selection, only if it brings higher reproductive success rate. For example, if a short-lived cat leaves more descendants than a long-lived cat, its genes will spread faster and will be favored by the natural selection. Since reproduction is at the core of propagation and vertical transmission of the genetic material, fitness generally refers to the reproductive fitness and every other fitness has no meaning in the evolutionary terms if it does not correlate with the reproductive fitness.

[Synchronized reproduction](#)

## Definition

The temporal clustering of reproductive events (mating, spawning, and/or births) among individuals in a population, colony, or social group.

## Description

Reproductive synchrony is widespread in plant and animal populations, encompassing phenomena as varied as the mass emergence of periodical cicadas, the colonial nesting of seabirds, and the synchronized menstrual cycles of female roommates. In its most straightforward form, synchrony may arise simply as an adaptive consequence of seasonality in climate or resources, since selection should favor individuals that produce young during advantageous conditions. Changes in photoperiod are thought to be the primary trigger for seasonal reproduction in terrestrial environments, often in combination with shorter-term cues such as food availability, rainfall, and temperature. However, as Ims (1990a, b) pointed out in a pair of seminal reviews, many instances of reproductive synchrony cannot be explained by seasonality alone, and these have inspired several alternative (and non-mutually exclusive) hypotheses for the selective pressures favoring reproductive synchrony, as well as its underlying proximate cues and physiological mechanisms.

One of the earliest and most powerful hypotheses for the evolution of reproductive synchrony

was proposed by Fraser Darling (1938), who found that the degree of nesting synchrony increased with colony size in herring gulls (*Larus argentatus*) and posited that synchronous nesting might increase individual offspring survival by reducing the per capita predation rate (the *predator swamping* or *predator satiation* hypothesis). There is widespread support for this hypothesis in the literature, and predation is now thought to be an important driver of reproductive synchrony in (for example) swarm emergences of aquatic insects, larval release of crabs and other marine organisms, and nesting aggregations of female ridley sea turtles (*Lepidochelys* spp.; Sweeney and Vannote 1982). In these examples, the selective advantage of predator satiation likely occurs at short timescales (within a single breeding season) and local spatial scales (within a single swarm or colony), simply as a consequence of safety in numbers. However, predator satiation has also been proposed as a potential driver of reproductive synchrony over larger spatial and temporal scales, as in the multi-year periodical emergences of cicadas (*Magicicada* spp.) and, in plants, the synchronized seed crops of masting trees and the mass flowering of bamboos (Kelly 1994). These examples are striking because cycles occur at the landscape scale – among geographically dispersed individuals in the population – and over remarkably long timescales (up to 17 years in cicadas, <10 years in most mast-seeding tree species, and up to 120 years in some bamboos). Clearly, predator satiation is only one of several factors influencing the evolution of these unusual life histories, and the selective pressures driving community-level synchrony are still under debate.

For species that defend their young, a secondary advantage to reproductive synchrony is efficient collective defense of spatially clumped broods (the *predator defense* hypothesis, Robinson 1985). Predator defense and predator satiation both predict that asynchronously produced offspring should suffer higher rates of predation, so it has been difficult to empirically distinguish between these two hypotheses. However, the coordinated defensive behaviors of many group-living animals – such as the remarkable

protective circles of female muskoxen around their calves and the collective mobbing behavior of colonially nesting seabirds – suggest that predator defense can be an important benefit of synchrony in some taxa.

*Mate availability* has also been proposed to influence the evolution of reproductive synchrony, but the direction of the correlation is conditional on the life history, population sex ratio, and mating system of the species in question. Emlen and Oring (1977) proposed that if mating opportunities are limited – for example, due to a biased sex ratio or widely dispersed individuals of the opposite sex – this should favor asynchronous reproduction. However, this prediction assumes that courtship and mating are time-consuming and is most relevant for species with some degree of biparental investment in the offspring. Most of the support for this hypothesis comes from studies of birds and mammals examining the covariation of synchrony and sex ratio within the same species. In promiscuous species lacking paternal care, by contrast, limited mate availability has been proposed to favor synchronized reproduction, particularly when individuals are short-lived and have few opportunities for reproduction. This pattern is best illustrated in the mass mating flights of ants (Hymenoptera), mayflies (Ephemeroptera), and other insects, in which locally high densities of receptive mates are thought to increase the odds of reproduction for individuals of both sexes. The hypothesis that simultaneous flowering in mast-seeding trees has evolved in order to maximize the chances of successful wind pollination is essentially the same concept applied to plants. In mast-seeding trees and swarming insects, both predator satiation and increased reproductive opportunities (via mating flights or wind pollination) likely favor synchrony, but the relative importance of the two factors is much debated (Kelly 1994).

Finally, *communal breeding* in animals also imposes strong selection for reproductive synchrony within social groups, albeit at smaller scales than the selective pressures discussed above. Since communally breeding females produce offspring together and provide cooperative care to the mixed brood of young, reproductive

synchrony is favored both by selection for group-level traits that increase the individual fitness of all breeders, such as efficient care of the communal brood, but also by competition between offspring in the brood. Young that are born after the majority of the brood may be at a competitive disadvantage, whereas young that are born early may be the target of aggression by group members that have not yet bred, favoring offspring that are produced synchronously (Riehl 2016). Reproductive synchrony is required for successful reproduction when the offspring must be gestated simultaneously (e.g., in communally nesting birds that produce a joint clutch) and enables alloparental lactation in socially breeding mammals. In many animals, including group-living birds, primates, felids, equids, and pinnipeds, synchronous reproduction has also been proposed as an adaptive strategy by females to avoid infanticide by males or by non-reproductive females within the social group, or as a nonadaptive consequence of cyclical takeovers by extra-group males (Gilchrist 2006).

*Proximate mechanisms* coordinating synchronized reproduction include both environmental and social cues. Seasonality in climate, leading to relatively predictable fluctuations in resources, synchronizes reproduction on broad scales in most animal populations. These physiological rhythms are largely under endogenous control, entrained by proximate environmental cues like photoperiod and temperature. In marine animals, including polychaetes, crustaceans, echinoderms, corals, and sponges (among others), synchronized gamete and larval release are also thought to be under endogenous control, with proximate entrainment by lunar, tidal, and light-dark cycles (Morgan and Christy 1995). By contrast, water temperature appears to be the salient trigger for mass emergences in freshwater aquatic insects in temperate regions, sometimes in concert with lunar cycling (Corbet 1964). Synchrony over multi-season timescales, such as the supra-annual reproduction of periodical cicadas and bamboos discussed above, is thought to be almost wholly dependent on endogenous rhythms, but little is known about the genetic or physiological underpinnings of these rhythms.

In social and colonial animals, local reproductive synchrony within the breeding season is often coordinated by behavioral cues, mediated through neuroendocrine pathways. Fraser Darling (1938) hypothesized that the positive correlation between colony size and reproductive synchrony in herring gulls was due to the visual and auditory stimulation of individuals coming into reproductive condition in close proximity, a type of social stimulation often referred to as the Darling or Fraser Darling effect.

## Reproductive System

Hare Krishna and Kishore Sesham

Department of Anatomy, All India Institute of Medical Sciences (AIIMS), Jodhpur, Rajasthan, India

## Synonyms

Genital system

## Definition

Reproductive system is the system of organs and its parts which are helping in reproduction and production of live offspring.

## Introduction

Reproductive system consists of male and female reproductive system. The male reproductive system consists of testes, vas deferens, seminal vesicles, ejaculatory ducts, prostate, and external genitalia. The female reproductive system comprises ovaries, uterine tubes, uterus, vagina, and external genitalia.

## Male Reproductive System

### Testis and Epididymis

The testes are a pair of ovoid organ which are suspended in the scrotum by the corresponding spermatic cord. In adult, their length = 4–5 cm, breadth = 2–3 cm, anteroposterior diameter = 3–4 cm, weight 12–20 g, and their average testicular volume = 15–25 ml (Standring 2016).

The testicular volume gradually increases in age 11–30 years and then remains constant between ages 30 and 60 years. But later, beyond 60 years of age, the testicular volume decreases slowly. The volume of the testis was found 31% smaller in men >75 years in comparison to those between 18 and 40 years of age (Gunes et al. 2016). These age-related changes in testes cause decrease in number of Leydig cells which is responsible for the increase of the follicle-stimulating hormone concentration and lower serum free testosterone (Mahmoud et al. 2003).

Left testis usually lies about 1 cm below the right testis. Each testis is covered by three layer from outer to inner side: (1) visceral layer of tunica vaginalis, (2) tunica albuginea, and (3) Tunica vasculosa (Datta 2010). Normally, there is a potential space between the visceral and parietal layer of tunica vaginalis which is filled by capillary straw coloured fluid. But, in certain conditions like inflammation, trauma, and tumour of testes, this thin film fluid can increase due to obstruction in lymphatic drainage and this condition is known as hydrocele (Standring 2016). Tunica albuginea forms mediastinum of testes interiorly which give rise to fibrous septa and divides the interior of testis into 250 lobules. Each lobule of testis contains one to four seminiferous tubules which is the site of spermatogenesis (Pawlina 2016). Normal spermatogenesis requires 3–4 °C lower temperature than abdominal cavity temperature. This lower temperature maintained by counter-current heat exchange system between pampiniform plexus and testicular arteries branches (Snell 2017).

The seminiferous tubules open into rete testis and rete testes communicates with upper end of epididymis through efferent ductules. The epididymis is comma-shaped structure overlying the superior posterolateral surface of the testis. Laterally, the visceral layer is tucked between the testis and epididymis which forms the sinus of epididymis. It consists of expanded head, body, and a pointed tail (Romanes 1998). The tail of epididymis further proceeds as continuation with the vas deferens. The main function of epididymis is absorption of fluid. It also helps in maturation of the sperm and secretion of substances in seminal fluid for nutrition of sperms (Snell 2017).

### Blood supply of testis and epididymis

1. Testicular artery which arises from abdominal aorta and it is a part of approximately two-thirds of the testicular blood supply.
2. Artery to vas deferens arises from superior vesical artery and cremasteric arteries arise from inferior epigastric artery, together they form approximately one-third of the testicular blood supply (Raman and Goldstein 2004).
